(Dated: January 2005)

The unpolarized spin-flip isoscalar generalized parton distribution function $(E^u + E^d)(x, \xi, t)$ is studied in the large-N_c limit at a low normalization point in the framework of the chiral quark-soliton model. This is the first study of generalized parton distribution functions in this model, which appear only at the subleading order in the large-N_c limit. Particular emphasis is put therefore on the demonstration of the theoretical consistency of the approach. The forward limit of $(E^u + E^d)(x, \xi, t)$ of which only the first moment – the anomalous isoscalar magnetic moment of the nucleon – is known phenomenologically, is computed numerically. Observables sensitive to $(E^u + E^d)(x, \xi, t)$ are discussed.

I. INTRODUCTION

The study of generalized parton distribution functions (GPDs) [1] (see [2–5] for reviews) promises numerous new insights in the internal structure of the nucleon [6–8]. GPDs can be accessed in a variety of hard exclusive processes [9] on which recently first data became available [10]. Current efforts [11] to understand and interpret the data rely, at the early stage of art, on modeling Ansätze for GPDs – which have to comply with the severe general constraints imposed by the polynomiality and positivity properties of GPDs [12, 13]. Model calculations [14–21] can provide important guidelines for such Ansätze – in particular in the case of those GPDs for which not even the forward limit is known from deeply inelastic scattering experiments. In this work we study the unpolarized GPD $E^a(x, \xi, t)$ in the chiral quark soliton model (χQSM) [22, 23].

The model describes the nucleon in a field theoretic framework in the limit of a large number of colours N_c as a chiral soliton of a static background pion field. Numerous nucleonic properties – among others form factors [24, 25] as well as quark and antiquark distribution functions [26–34] – have been described in this model without adjustable parameters, typically to within an accuracy of $(10 - 30)\%$. The field-theoretical character is a crucial feature of the χQSM which is responsible for the wide range of applicability and which guarantees the theoretical consistency of the approach. In Refs. [15–17] it was demonstrated that the χQSM consistently describes those GPDs, which are of leading order in the large N_c-limit.

In this work we extend the formalism of Ref. [15] to the description of unpolarized GPDs which appear only at subleading order in the large-N_c expansion. We pay particular attention to the demonstration of the consistency of the approach. After checking explicitly that the model expressions for GPDs satisfy polynomiality, relevant sum rules, etc. we focus on the flavour combination of $E^a(x, \xi, t)$ subleading in large-N_c, namely the flavour singlet, which – being related to the spin sum rule of the nucleon – is of particular phenomenological interest. The corresponding flavour structure $(E^u - E^d)(x, \xi, t)$, which is leading in N_c, was already studied in Ref. [15] (*cf.* [4]). An interesting issue we shall finally address is, which hard exclusive reactions are particularly sensitive to the GPD $(E^u + E^d)(x, \xi, t)$. We observe that target single transverse spin asymmetries in two pion production are most promising in this respect.

This note is organized as follows. After a general discussion of the properties of GPDs in Sec. II and a short introduction to the χQSM in Sec. III, we review in Sec. IV the formalism of the χQSM for GPDs of leading order in N_c. In Sec. V we generalize the approach to the case of GPDs subleading in N_c, and check its consistency. In Sec. VI we apply the approach to the numerical calculation of the forward limit of $(E^u + E^d)(x, \xi, t)$ and discuss phenomenological implications from our result in Sec. VII. Finally, Sec. VIII contains a summary and conclusions. Technical details on the calculations can be found in the Appendices.

II. THE UNPOLARIZED GENERALIZED PARTON DISTRIBUTION FUNCTIONS

The unpolarized quark GPDs in the proton are defined as

$$\begin{aligned}\int\frac{\mathrm{d}\lambda}{2\pi}\, e^{i\lambda x}\langle\mathbf{P}',s'|\bar\psi_q(-\tfrac{\lambda n}{2})\not{n}\,[-\tfrac{\lambda n}{2},\tfrac{\lambda n}{2}]\psi_q(\tfrac{\lambda n}{2})|\mathbf{P},s\rangle \\ = H^q(x,\xi,t)\,\bar U(\mathbf{P}',s')\not{n}\,U(\mathbf{P},s) \\ +E^q(x,\xi,t)\,\bar U(\mathbf{P}',s')\,\frac{i\sigma^{\mu\nu}n_\mu\Delta_\nu}{2M_N}\,U(\mathbf{P},s),\end{aligned} \tag{1}$$

where $[z_1, z_2]$ denotes the gauge-link, and the renormalization scale dependence is not indicated for brevity. The light-like vector n^μ satisfies $n(P'+P)=2$. The skewedness parameter ξ, the four-momentum transfer Δ^μ and the Mandelstam variable t are defined as $\Delta^\mu=(P'-P)^\mu$, $n\Delta=-2\xi$, $t=\Delta^2$. The antiquark distributions are given by $H^{\bar q}(x,\xi,t)=-H^q(-x,\xi,t)$ and similarly for $E^{\bar q}(x,\xi,t)$. The unpolarized GPDs are normalized to the corresponding elastic (Dirac- and Pauli-) form factors

$$\int_{-1}^{1}\mathrm{d}x\; H^q(x,\xi,t)=F_1^q(t)\;,\quad \int_{-1}^{1}\mathrm{d}x\; E^q(x,\xi,t)=F_2^q(t)\;. \tag{2}$$

The relations (2) are special cases of the polynomiality property [2] which follows from hermiticity, parity, time reversal and Lorentz invariance, and implies that the $N^{\rm th}$ Mellin moment of an unpolarized GPDs is a polynomial in even powers of ξ of degree less than or equal to N

$$\int_{-1}^{1}\mathrm{d}x\; x^{N-1}\,H^q(x,\xi,0)=h_0^{q\,(N)}+h_2^{q\,(N)}\xi^2+\ldots+\begin{cases}h_N^{q\,(N)}\xi^N & \text{for } N \text{ even}\\ h_{N-1}^{q\,(N)}\xi^{N-1} & \text{for } N \text{ odd,}\end{cases} \tag{3}$$

$$\int_{-1}^{1}\mathrm{d}x\; x^{N-1}\,E^q(x,\xi,0)=e_0^{q\,(N)}+e_2^{q\,(N)}\xi^2+\ldots+\begin{cases}e_N^{q\,(N)}\xi^N & \text{for } N \text{ even}\\ e_{N-1}^{q\,(N)}\xi^{N-1} & \text{for } N \text{ odd.}\end{cases} \tag{4}$$

As a consequence of the spin $\frac{1}{2}$ nature of the nucleon the coefficients in front of the highest power in ξ for even moments N are related to each other by

$$h_N^{q\,(N)}=-\,e_N^{q\,(N)}=\int_{-1}^{1}\mathrm{d}z\; z^{N-1}D^q(z)\;\;, \tag{5}$$

and arise from the so-called D-term $D^q(z)$ with $z=x/\xi$ which has finite support only for $|x|<|\xi|$ [35]. The D-term governs the asymptotics of unpolarized GPDs in the limit of a large renormalization scale [4] and is related to the distribution of the pressure and shear forces acting on the partons in the nucleon [8].

In the large-N_c limit different flavour combinations of GPDs and of the D-term exhibit the behaviour [4]

$$\begin{aligned}(H^u+H^d)(x,\xi,t)&=N_c^2 f(N_cx,N_c\xi,t)\;, &(H^u-H^d)(x,\xi,t)&=N_c\,f(N_cx,N_c\xi,t)\;,\\ (E^u+E^d)(x,\xi,t)&=N_c^2 f(N_cx,N_c\xi,t)\;, &(E^u-E^d)(x,\xi,t)&=N_c^3 f(N_cx,N_c\xi,t)\;,\\ (D^u+D^d)(z)&=N_c^2 f(z) &,\quad (D^u-D^d)(z)&=N_c\,f(z)\;\;.\end{aligned} \tag{6}$$

The functions $f(u,v,t)$ and $f(z)$ (which are of order $\mathcal{O}(N_c^0)$ and which we do not distinguish for notational simplicity) are stable in the large-N_c limit for fixed values of u, v, z, $t=\mathcal{O}(N_c^0)$. $E^q(x,\xi,t)$ is systematically enhanced by one order in N_c with respect to $H^q(x,\xi,t)$ due to the nucleon mass $M_N=\mathcal{O}(N_c)$ appearing in the denominator on the right hand side of Eq. (1). As a consequence the flavour combination of $H^q(x,\xi,t)$ leading in N_c, namely $(H^u+H^d)(x,\xi,t)$, and the flavour combination of $E^q(x,\xi,t)$ subleading in N_c, namely $(E^u+E^d)(x,\xi,t)$, have the same order in N_c. This is natural from the point of view of the spin sum rule [6]

$$\int_{-1}^{1}\mathrm{d}x\;\, x\sum_{q=u,d,\ldots}(H^q+E^q)(x,\xi,t)=2J^Q\;, \tag{7}$$

where $2J^Q$ is the fraction of the nucleon spin due to (spin and orbital angular momentum of) quarks. The flavour singlets of $E^q(x,\xi,t)$ and $H^q(x,\xi,t)$ enter the left-hand-side of (7) and contribute on equal footing in the large-N_c limit to $J^Q=\mathcal{O}(N_c^0)$.

In the forward limit of $H^q(x,\xi,t)$ we recover the unpolarized parton distribution function $f_1^q(x)$

$$\lim_{\substack{\xi\to 0\\ t\to 0}} H^q(x,\xi,t) = f_1^q(x)\ . \tag{8}$$

The GPD $E^q(x,\xi,t)$ has also a well defined forward limit which, however, is not accessible in deeply inelastic lepton nucleon scattering. Phenomenologically only the first moment of $E^q(x,0,0)$ is known which is given by the anomalous magnetic moment $\kappa^q \equiv F_2^q(0)$ with

$$\int\limits_0^1 \mathrm{d}x\,(E^u - E^{\bar u})(x,0,0) = \kappa_u = 1.673\,,\quad \int\limits_0^1 \mathrm{d}x\,(E^d - E^{\bar d})(x,0,0) = \kappa_d = -2.033\,. \tag{9}$$

III. THE CHIRAL QUARK-SOLITON MODEL (χQSM)

The effective chiral relativistic field theory underlying the χQSM is given by the partition function [36, 37]

$$Z_{\rm eff} = \int \mathcal{D}\psi\,\mathcal{D}\bar\psi\,\mathcal{D}U\ \exp\biggl(i\int \mathrm{d}^4x\ \bar\psi\,(i\partial\!\!\!/ - M\,U^{\gamma_5})\psi\biggr)\,, \tag{10}$$

where ψ and $U = \exp(i\tau^a\pi^a)$ are the $SU(2)$ chiral quark and pion fields with $U^{\gamma_5} \equiv \exp(i\gamma_5\tau^a\pi^a)$, and M is the dynamical quark mass. The effective theory (10) was derived from the instanton model of the QCD vacuum [37, 38]. An important small parameter in this derivation is the instanton packing fraction $\rho_{\rm av}/R_{\rm av} \sim \frac{1}{3}$ of the dilute instanton medium, where $\rho_{\rm av}$ and $R_{\rm av}$ are respectively the average size and separation of instantons. The effective theory (10) contains the Weinberg-Gasser-Leutwyler Lagrangian and the Wess-Zumino term with correct coefficients and is valid for momenta below a scale set by the inverse of the average instanton size $\rho_{\rm av}^{-1} \approx 600\,\mathrm{MeV}$. At this scale the dynamical quark mass M, which in general is momentum dependent, drops to zero. In numerical calculations it is often convenient to consider constant M and to apply an appropriate regularization method with a UV-cutoff of the order of magnitude of $\rho_{\rm av}^{-1}$. In calculations of (some) GPDs, however, it is important to consider momentum dependent M [15].

In the large-N_c limit, which allows to solve the functional integral over pion field configurations in the saddle-point approximation, the effective theory in Eq. (10) describes the nucleon as a classical soliton of the pion field [22] providing a practical realization of the large-N_c picture of the nucleon [39]. Quarks are described by one-particle wave functions which are the solutions of the Dirac equation in the background of the static pion field

$$\hat H_{\rm eff}|n\rangle = E_n|n\rangle\ \ ,\quad \hat H_{\rm eff} = -i\gamma^0\gamma^k\partial_k + \gamma^0 M U^{\gamma_5}\ . \tag{11}$$

The spectrum of the effective Hamiltonian (11) consists of an upper and a lower Dirac continuum, which are distorted by the background field compared to the continua of the free Hamiltonian $\hat H_0 = -i\gamma^0\gamma^k\partial_k + \gamma^0 M$, and of a discrete bound state level of energy $E_{\rm lev}$. By occupying the discrete level and the states of lower continuum each by N_c quarks in an anti-symmetric colour state, one obtains a state with unity baryon number called soliton. The minimization of the soliton energy $E_{\rm sol}$ with respect to variations of the chiral field U yields the self-consistent pion field U_c, which for symmetry reasons has the "hedgehog" structure $U_c(\mathbf{x}) = \exp[i\mathbf{e_r}\boldsymbol{\tau}P(r)]$ where $P(r)$ is the soliton profile with $r = |\mathbf{x}|$ and $\mathbf{e_r} = \mathbf{x}/r$. The mass of the nucleon is given by

$$M_N = E_{\rm sol}[U_c] = \min_U E_{\rm sol}[U]\,,\quad E_{\rm sol}[U] = N_c\biggl(E_{\rm lev} + \sum_{E_n<0}(E_n - E_{n_0})\biggr)_{\rm reg}\ . \tag{12}$$

The soliton energy is (for constant M) logarithmically UV-divergent and has to be regularized – as indicated in Eq. (12) and described in Ref. [25].

In order to include $1/N_c$ corrections one has to consider quantum fluctuations around the saddle point solution. Hereby the (translational and rotational) zero modes of the soliton solution are the only taken into account. In particular one considers time-dependent rotations of the hedgehog field, $U_c(\mathbf{x}) \to R(t)U_c(\mathbf{x})R^\dagger(t)$, where the collective coordinate $R(t)$ is a rotation matrix in SU(2)-flavour space. The path integration over the collective coordinates can be solved by expanding in powers of the collective angular velocity $\Omega \equiv -iR^\dagger\partial_t R$ which corresponds to an $1/N_c$ expansion. The latter is justified, since the soliton moment of inertia,

$$I = \frac{N_c}{6}\sum_{\substack{n,\,\rm occ\\ j,\,\rm non}} \frac{\langle n|\tau^a|j\rangle\langle j|\tau^a|n\rangle}{E_j - E_n}, \tag{13}$$

is large, namely $I = \mathcal{O}(N_c)$, and the soliton rotation is therefore slow. (In Eq. (13) one has to sum over occupied ("occ") states n, i.e. over states with $E_n \le E_{\rm lev}$, and over non-occupied ("non") states j, i.e. over states with $E_j > E_{\rm lev}$.) This procedure – which is referred to as quantization of zero modes – assigns to the soliton a definite momentum and spin-isospin quantum numbers [22].

The effective theory (10) allows to derive by means of path integral methods unambiguous model expressions for nucleon matrix elements of QCD quark bilinear operators sandwiched in nucleon states $\langle N'|\bar\psi(z_1)[z_1,z_2]\Gamma\psi(z_2)|N\rangle$, where Γ is some matrix in Dirac- and flavour space. For local observables such as, e.g., form factors the gauge link reduces to a unity matrix in colour space. When evaluating non-local operators in the model – as they appear in GPDs – it is crucial that the effects of gluonic degrees of freedom, which are intrinsic in the gauge link, appear strongly suppressed with respect to quark degrees of freedom. This is true for twist-2 [40] (and certain twist-3 operators [41]) and guarantees the colour gauge invariance of the model calculation.

If in QCD $\langle N'|\bar\psi(z_1)[z_1,z_2]\Gamma\psi(z_2)|N\rangle$ is scale dependent then the model result corresponds to low a scale of $\rho^{-1}\approx 600\,{\rm MeV}$. In this way static nucleonic observables [24, 25], twist-2 quark and anti-quark distribution functions [26–34] have been computed in the χQSM and found to agree to within $(10-30)\%$ with experimental data or phenomenological parameterizations. In [15, 16] the approach was generalized to describe GPDs. The results of the χQSM respect all general counting rules of the large-N_c phenomenology.

IV. GPDS IN LEADING ORDER OF LARGE N_c

It is convenient to treat the cases of flavour singlet and non-singlet quantities in the model separately for symmetry reasons. Let us introduce the notation

$$\mathcal{M}^{(I=0)}_{s's} \equiv \int\frac{{\rm d}\lambda}{2\pi}\,e^{i\lambda x}\langle\mathbf{P}',s'|\bar\psi(-\tfrac{\lambda n}{2})\,\not{n}\,\psi(\tfrac{\lambda n}{2})|\mathbf{P},s\rangle \tag{14}$$

$$\mathcal{M}^{(I=1)}_{s's} \equiv \int\frac{{\rm d}\lambda}{2\pi}\,e^{i\lambda x}\langle\mathbf{P}',s'|\bar\psi(-\tfrac{\lambda n}{2})\,\tau^3\not{n}\,\psi(\tfrac{\lambda n}{2})|\mathbf{P},s\rangle\;. \tag{15}$$

The $\mathcal{M}^{(I)}_{s's}$ are 2×2-matrices in spin indices which have the following behaviour in the large-N_c limit

$$\begin{aligned}{\rm tr}\,\{\mathcal{M}^{(I=0)}\} &= \mathcal{O}(N_c^2)\;,\quad {\rm tr}\,\{\sigma^m\mathcal{M}^{(I=0)}\} = \mathcal{O}(N_c)\;,\\ {\rm tr}\,\{\mathcal{M}^{(I=1)}\} &= \mathcal{O}(N_c)\;,\quad {\rm tr}\,\{\sigma^m\mathcal{M}^{(I=1)}\} = \mathcal{O}(N_c^2)\;.\end{aligned} \tag{16}$$

These relations do not follow from the dynamics of the model, but are group theoretical consequences of the spin-flavour structure of the (hedgehog) soliton field. In this sense the relations (16) are model-independent large-N_c results of QCD [42] which are consequently respected in the χQSM.

In order to evaluate the bi(nucleon-)spinor expression on the right-hand-side of Eqs. (1) one has to consider that in the large N_c limit the nucleon is heavy, $M_N = \mathcal{O}(N_c)$, and the kinematics becomes non-relativistic. In particular we have for the components of the momentum transfer $\Delta^i = \mathcal{O}(N_c^0)$ and $\Delta^0 = \mathcal{O}(N_c^{-1})$. Thus the hierarchy holds $M_N \gg |\Delta^i| \gg |\Delta^0|$, while $t = -\mathbf{\Delta}^2 = \mathcal{O}(N_c^0)$ and $\xi = -\Delta^3/(2M_N) = \mathcal{O}(N_c^{-1})$. Here we have chosen $n^\mu = (1,0,0,-1)/M_N$. Evaluating consequently the right-hand-side of Eq. (1) in this large-N_c kinematics yields for the flavour-singlet and non-singlet case, respectively,

$$\mathcal{M}^{(I=0)}_{s's} = 2\,\delta_{ss'}\,(H^u+H^d)(x,\xi,t) - \frac{i\epsilon^{3kl}\Delta^k}{M_N}(\sigma^l)_{s's}\Big[(H^u+H^d)(x,\xi,t)+(E^u+E^d)(x,\xi,t)\Big]\;, \tag{17}$$

$$\mathcal{M}^{(I=1)}_{s's} = 2\,\delta_{ss'}\,\Big[(H^u-H^d)(x,\xi,t)+\frac{t}{4M_N^2}(E^u-E^d)(x,\xi,t)\Big] - \frac{i\epsilon^{3kl}\Delta^k}{M_N}(\sigma^l)_{s's}(E^u-E^d)(x,\xi,t)\;. \tag{18}$$

From Eqs. (17, 18) simple relations follow for the leading (in the large-N_c counting) GPDs

$$(H^u+H^d)(x,\xi,t) = \frac{1}{4}\,{\rm tr}\{\mathcal{M}^{(I=0)}\}\;, \tag{19}$$

$$(E^u-E^d)(x,\xi,t) = \frac{iM_N\epsilon^{3bm}\Delta^b}{2\,\mathbf{\Delta}_\perp^2}\,{\rm tr}\,\{\sigma^m\mathcal{M}^{(I=1)}\}\;, \tag{20}$$

where "tr" denotes the trace over spin indices and $\mathbf{\Delta}_\perp^2 = \mathbf{\Delta}^2-(\Delta^3)^2 = -t-4M_N^2\xi^2$. The subleading structures, however, appear only in combination with the leading ones

$$(H^u+H^d)(x,\xi,t)+(E^u+E^d)(x,\xi,t) = \frac{iM_N\epsilon^{3bm}\Delta^b}{2\,\mathbf{\Delta}_\perp^2}\,{\rm tr}\{\sigma^m\mathcal{M}^{(I=0)}\}\;, \tag{21}$$

$$(H^u-H^d)(x,\xi,t)+\frac{t}{4M_N^2}\,(E^u-E^d)(x,\xi,t) = \frac{1}{4}{\rm tr}\{\mathcal{M}^{(I=1)}\}\;. \tag{22}$$

The structures in the square brackets of Eqs. (17, 18) and on the left-hand-sides of Eqs. (21, 22) are analogs of the relations between the electric and magnetic form factors $G_E^q(t)$, $G_M^q(t)$ and the Dirac- and Pauli-form factors $F_1^q(t)$, $F_2^q(t)$, which are given by

$$G_E^q(t) = F_1^q(t) + F_2^q(t)\,, \quad G_M^q(t) = F_1^q(t) + \frac{t}{4M_N^2}\,F_2^q(t)\,. \tag{23}$$

The model expressions for $\mathcal{M}^{(I=0,1)}$ in leading order of the large-N_c limit were derived in Ref. [15] and the following results for $(H^u+H^d)(x,\xi,t)$ and (E^u-E^d) were obtained using Eqs. (17, 18)

$$\begin{aligned}(H^u+H^d)(x,\xi,t) &= M_N N_c \int\frac{\mathrm{d}z^0}{2\pi}\sum_{n,\mathrm{occ}} e^{iz^0(xM_N-E_n)} \\ &\quad\times\langle n|\,(1+\gamma^0\gamma^3)\exp(-i\tfrac{z^0}{2}\hat{p}^3)\exp(i\mathbf{\Delta}\hat{\mathbf{X}})\exp(-i\tfrac{z^0}{2}\hat{p}^3)\,|n\rangle\,,\end{aligned} \tag{24}$$

$$\begin{aligned}(E^u-E^d)(x,\xi,t) &= \frac{2iM_N^2N_c}{3(\mathbf{\Delta}^\perp)^2}\int\frac{\mathrm{d}z^0}{2\pi}\sum_{n,\mathrm{occ}} e^{iz^0(xM_N-E_n)} \\ &\quad\times\langle n|\,(1+\gamma^0\gamma^3)(\boldsymbol{\tau}\times\mathbf{\Delta})^3\exp(-i\tfrac{z^0}{2}\hat{p}^3)\exp(i\mathbf{\Delta}\hat{\mathbf{X}})\exp(-i\tfrac{z^0}{2}\hat{p}^3)\,|n\rangle\,.\end{aligned} \tag{25}$$

There are equivalent expressions with $\sum_{\mathrm{occ}} \to -\sum_{\mathrm{non}}$, i.e. where the summation goes over non-occupied states $E_n > E_{\mathrm{lev}}$. The possibility of computing in the model quantities in these two independent ways is deeply related to the locality properties of the model [26]. Numerical results for (24, 25) were presented in Ref. [15], and further discussed and reviewed in Ref. [4].

Let us emphasize that according to Eq. (8) in the forward limit the right-hand-side of (24) reduces to the model expression for $(f_1^u+f_1^d)(x)$ [15]. $(H^u+H^d)(x,\xi,t)$ and $(E^u-E^d)(x,\xi,t)$ are correctly normalized to the respective form factors [15], *cf.* Eq. (2), and they satisfy the polynomiality conditions in Eqs. (3, 4) [17].

It is worthwhile mentioning that the coefficient of the highest power in ξ of even Mellin moments of $(E^u-E^d)(x,\xi,t)$ in leading order of large N_c is zero in the χQSM. Also this result is not a dynamical feature of the model, but rather a group theoretical consequence of the soliton symmetries which ensure the correct large-N_c counting for the flavour-nonsinglet D-term. In fact, if this coefficient were not zero, then $(E^u-E^d)=\mathcal{O}(N_c^3)$ would imply $(D^u-D^d)=\mathcal{O}(N_c^3)$ in conflict with the counting rule which states $(D^u-D^d)=\mathcal{O}(N_c)$, *cf.* Eq. (6).

V. GPDS IN SUBLEADING ORDER OF LARGE N_c

One has to consider $1/N_c$ (rotational) corrections to $\mathcal{M}^{(I=0,1)}$ in order to study the subleading flavour combinations $(H^u-H^d)(x,\xi,t)$ and $(E^u+E^d)(x,\xi,t)$. In order to simplify the notation let us introduce

$$E_M(x,\xi,t) = (H^u+H^d)(x,\xi,t) + (E^u+E^d)(x,\xi,t) \sim \mathcal{O}(N_c^2)\,, \tag{26}$$

$$H_E(x,\xi,t) = (H^u-H^d)(x,\xi,t) + (E^u-E^d)(x,\xi,t)\,\frac{t}{4M_N^2} \sim \mathcal{O}(N_c)\,. \tag{27}$$

Here the respective already known (see above) flavour combinations of $H^q(x,\xi,t)$ and $E^q(x,\xi,t)$ leading in N_c appear. Thus it is sufficient to focus on the "new" objects $E_M(x,\xi,t)$ and $H_E(x,\xi,t)$.

The model expressions for $H_E(x,\xi,t)$ and $E_M(x,\xi,t)$ (for a proton) read

$$\begin{aligned}H_E(x,\xi,t) &= -\frac{M_NN_c}{12I}\int\frac{\mathrm{d}z^0}{2\pi}\Biggl[\Biggl\{\sum_{\substack{m,\mathrm{occ}\\ j,\mathrm{all}\\ m\neq j}} e^{-iz^0E_m} - \sum_{\substack{m,\mathrm{all}\\ j,\mathrm{occ}\\ m\neq j}} e^{-iz^0E_j}\Biggr\}\frac{1}{E_m-E_j} + \frac{\partial}{\partial xM_N}\sum_{\substack{m,\mathrm{occ}\\ j,\mathrm{all}\\ m\neq j}} e^{-iz^0E_m}\Biggr]e^{iz^0xM_N} \\ &\quad\times\langle m|\tau^a|j\rangle\,\langle j|\,\tau^a(1+\gamma^0\gamma^3)\,\exp(-iz^0\hat{p}^3/2)\,\exp(i\mathbf{\Delta}\hat{\mathbf{X}})\,\exp(-iz^0\hat{p}^3/2)\,|m\rangle\,,\end{aligned} \tag{28}$$

$$\begin{aligned}E_M(x,\xi,t) &= \frac{iM_N^2N_c}{2I}\int\frac{\mathrm{d}z^0}{2\pi}\Biggl[\Biggl\{\sum_{\substack{m,\mathrm{occ}\\ j,\mathrm{all}\\ m\neq j}} e^{-iz^0E_m} - \sum_{\substack{m,\mathrm{all}\\ j,\mathrm{occ}\\ m\neq j}} e^{-iz^0E_j}\Biggr\}\frac{1}{E_m-E_j} + \frac{\partial}{\partial xM_N}\sum_{\substack{m,\mathrm{occ}\\ j,\mathrm{all}\\ m\neq j}} e^{-iz^0E_m}\Biggr]e^{iz^0xM_N} \\ &\quad\times\langle m|\tau^b|j\rangle\,\langle j|\,(1+\gamma^0\gamma^3)\,\exp(-iz^0\hat{p}^3/2)\,\frac{\epsilon^{3ab}\Delta^a}{\mathbf{\Delta}_\perp^2}\,\exp(i\mathbf{\Delta}\hat{\mathbf{X}})\,\exp(-iz^0\hat{p}^3/2)\,|m\rangle\,.\end{aligned} \tag{29}$$

There are equivalent expressions with opposite sign where the summations go over non-occupied states. Considering the generalizations due to the off-forward kinematics [15, 16], the derivations of Eqs. (28, 29) closely follow the derivations of the model expression for the flavour non-singlet unpolarized distribution $(f_1^u-f_1^d)(x)$ [30] and the flavour-singlet helicity $(g_1^u+g_1^d)(x)$ and transversity $(h_1^u+h_1^d)(x)$ distribution functions [33]. In the following we check explicitly the theoretical consistency of the expressions (28, 29).

A. Form factors and polynomiality

Let us first verify the correct normalization of $H_E(x,\xi,t)$ and $E_M(x,\xi,t)$. In order to integrate Eqs. (28, 29) over x it is convenient to substitute $x \to y = xM_N$ and to extend the y-integration range $[-M_N, M_N]$ to $[-\infty,\infty]$ in the large-N_c limit. The derivative in x drops out and after cancellations in the curly brackets in Eqs. (28, 29) only summations over occupied states $|m\rangle$ and non-occupied states $|j\rangle$ and vice versa remain, which can be combined by exploring model symmetries, see App. A. We obtain

$$\begin{aligned}\int\limits_{-1}^{1} \mathrm{d}x\, H_E(x,\xi,t) &= -\frac{N_c}{6I}\sum_{\substack{m,\text{occ}\\ j,\text{non}}} \frac{1}{E_m-E_j}\,\langle m|\tau^a|j\rangle\,\langle j|\,\tau^a\,\exp(i\mathbf{\Delta}\hat{\mathbf{X}})\,|m\rangle \equiv G_E^{(I=1)}(t)\;,\\ \int\limits_{-1}^{1} \mathrm{d}x\, E_M(x,\xi,t) &= \frac{N_cM_N}{2I\mathbf{\Delta}^2}\sum_{\substack{m,\text{occ}\\ j,\text{non}}} \frac{i\epsilon^{abc}\Delta^a}{E_m-E_j}\,\langle m|\tau^b|j\rangle\,\langle j|\,\gamma^0\gamma^c\exp(i\mathbf{\Delta}\hat{\mathbf{X}})\,|m\rangle \equiv 3\,G_M^{(I=0)}(t)\;,\end{aligned} \tag{30}$$

where we identify the model expressions for the electric isovector $G_E^{(I=1)}(t)$ and magnetic isoscalar $G_M^{(I=0)}(t)$ form factors [24, 25]. [The factor 3 in the second line of (30) appears because for GPDs the notion of (non-) singlet commonly refers to quark flavours, e.g. (H^u+H^d). In contrast, in the case of form factors it refers to proton and neutron, e.g. $G_M^{(I=0)} \equiv G_M^p + G_M^n$.] From (23, 26, 27, 30) and recalling that the leading large-N_c GPDs $(H^u+H^d)(x,\xi,t)$ and $(E^u-E^d)(x,\xi,t)$ are correctly normalized [15], we find for the subleading GPDs in agreement with Eq. (2)

$$\int\limits_{-1}^{1} \mathrm{d}x\,(H^u-H^d)(x,\xi,t) = (F_1^u-F_1^d)(t)\,,\quad \int\limits_{-1}^{1} \mathrm{d}x\,(E^u+E^d)(x,\xi,t) = (F_2^u+F_2^d)(t)\,. \tag{31}$$

In App. B it is explicitly demonstrated that the higher moments in x of $H_E(x,\xi,t)$ and $E_M(x,\xi,t)$ are even polynomials in ξ according to (3, 4). In fact, we find that in even moments the coefficients in front of the highest power in ξ have opposite sign in $(E^u+E^d)(x,\xi,t)$ and $(H^u+H^d)(x,\xi,t)$ in accordance with the relation (5).

B. Spin sum rule

For the second moment of $E_M(x,\xi,t)$ at $t=0$ we obtain in the χQSM, cf. App. C

$$\int_{-1}^{1} \mathrm{d}x\; xE_M(x,\xi,0) = 2S^Q + 2L^Q = 2S^N = 1\;, \tag{32}$$

where $S^N = \frac{1}{2}$ is the total spin of the nucleon, and S^Q and L^Q are the respective contributions of the spin and orbital angular momentum of quarks and antiquarks to the nucleon spin. The result in Eq. (32) is consistent. In the effective theory the contribution of quark and antiquark degrees of freedom, $J^Q = S^Q + L^Q$, must account entirely for the nucleon spin, since there are no gluons in the model. Thus, the result in (32) means that the spin sum rule (7) is consistently fulfilled in the model:

$$\int\limits_{-1}^{1} \mathrm{d}x\; x(H^u+H^d+E^u+E^d)(x,\xi,0) = 2J^Q = 1\;. \tag{33}$$

We note that in the model $2S^Q = g_A^{(0)} = 0.35$ where $g_A^{(0)}$ denotes the isosinglet axial coupling constant [33]. Thus, in the χQSM 35% of the nucleon spin are due to the quark spin, while 65% are due to the orbital angular momentum of quarks and antiquarks.

In a gauge theory it is not possible to separate unambiguously spin and orbital momentum [43, 44]. It also is by no means clear that the identification of the model expression for quark orbital momentum in Eq. (32) is unambiguous. It is interesting to note that one arrives at the same result by intuitively identifying $\hat{L}^i = \epsilon^{ijk}\hat{x}^j\hat{p}^k$ with the orbital angular momentum operator of the effective theory (10), cf. [45]. However, one has to keep in mind that this issue can rigorously be studied in the instanton vacuum model from which the χQSM was derived. Noteworthy in this context is that $g_A^{(0)}$ in the chiral quark soliton model arises from the realization of the axial anomaly in the instanton vacuum [40].

Since in the chiral quark-soliton model also the total momentum of the nucleon is carried by quarks and antiquarks only [26], i.e. $M^Q = 1$, we obtain for the second moment of $(E^u+E^d)(x,0,0)$ the result

$$\int\limits_{-1}^{1} \mathrm{d}x\; x(E^u+E^d)(x,0,0) = (2J^Q - M^Q) = 0\;. \tag{34}$$

Interestingly, the result (34) holds also in QCD in the asymptotic limit of a large normalization scale $\mu \to \infty$. This happens because M^Q and $2J^Q$ have the same asymptotics [43]

$$\lim_{\mu\to\infty} M^Q = \lim_{\mu\to\infty} (2J^Q) = \frac{3N_F}{16+3N_F} \tag{35}$$

where N_F is the number of quark flavours. It should be stressed, however, that at a low scale $\mu \sim 600\,\mathrm{MeV}$ in the model $M^Q = 2J^Q = 1$ is far from the asymptotic values in Eq. (35).

Eq. (34) is the general prediction of any model lacking explicit gluon degrees of freedom, which is able to consistently describe the nucleon in terms of quark and antiquark degrees of freedom – such as the χQSM. One can show, using methods of theory of the instanton vacuum [40] that the gluon contribution to the nucleon momentum and angular momentum is parametrically suppressed by the packing fraction of the instantons in the vacuum. Therefore in order to obtain non-zero gluon contributions one has to extend χQSM beyond the leading order in the instanton packing fraction.

Noteworthy, it has been argued that momentum and angular momentum should be equally distributed among quarks and gluons at *any scale*, not only in the asymptotic limit (35), an observation which can be reformulated as the absence of an anomalous gravitomagnetic moment of the nucleon [46].

C. Forward limit

Finally let us discuss the forward limit. From (27) we see that $H_E(x,0,0) = (H^u - H^d)(x,0,0)$. Indeed, taking $\mathbf{\Delta} \to 0$ in Eq. (28) and making use of the hedgehog symmetry we recover, in agreement with Eq. (8), the model expression for the flavour non-singlet unpolarized distribution function [30]

$$H_E(x,0,0) = \frac{M_N N_c}{12I} \sum_{\substack{m,\mathrm{occ}\\ j,\mathrm{all}\\ m\neq j}} \left[\frac{2}{E_j - E_m} - \frac{\partial}{\partial x M_N}\right] \langle m|\tau^a|j\rangle \, \langle j|\, \tau^a (1+\gamma^0\gamma^3)\, \delta(xM_N - E_m - \hat{p}^3)\, |m\rangle \equiv (f_1^u - f_1^d)(x). \tag{36}$$

The forward limit of $E_M(x,\xi,t) \to (E^u + E^d)(x,0,0) + (f_1^u + f_1^d)(x)$ contains a contribution which is a priori not known, namely $(E^u + E^d)(x,0,0)$. Therefore we derive here the model expression for $E_M(x,0,0)$ which we shall study below in detail. The limit $\xi \to 0$ is regular[1], however, to complete the forward limit we have to consider with care the limit $\mathbf{\Delta}_\perp \to 0$ of the structure

$$\frac{\epsilon^{3jk}\Delta_\perp^j}{\mathbf{\Delta}_\perp^2} \exp(i\mathbf{\Delta}_\perp \hat{\mathbf{X}}_\perp) = \epsilon^{3jk}\,\frac{\Delta_\perp^j}{\mathbf{\Delta}_\perp^2} + i\epsilon^{3jk}\hat{X}_\perp^m\,\frac{\Delta_\perp^j\Delta_\perp^m}{\mathbf{\Delta}_\perp^2} + \mathcal{O}(\Delta^k)\ . \tag{37}$$

The first term in the above expansion (for small but non-zero $\mathbf{\Delta}_\perp$) yields a vanishing result when inserted into Eq. (29) due to the hedgehog symmetry. The second term from the expansion in (37) yields the only contribution which survives the forward limit in Eq. (29). Making use of

$$\lim_{\mathbf{\Delta}_\perp\to 0} \frac{\Delta_\perp^j\Delta_\perp^m}{\mathbf{\Delta}_\perp^2} = \frac{1}{2}\,\delta_\perp^{jm} \equiv \frac{1}{2}\,(\delta^{jm} - \delta^{j3}\delta^{m3}) \tag{38}$$

we obtain upon use of hedgehog symmetry

$$E_M(x,0,0) = \frac{M_N^2 N_c}{4I}\,\epsilon^{3jk} \sum_{\substack{m,\mathrm{occ}\\ j,\mathrm{all}\\ m\neq j}} \left[\frac{2}{E_j - E_m} - \frac{\partial}{\partial x M_N}\right] \langle m|\tau^k|j\rangle \, \langle j|\,(1+\gamma^0\gamma^3)\,\delta(xM_N - E_m - \hat{p}^3)\,\hat{X}_\perp^j\,|m\rangle\ . \tag{39}$$

As a final check we integrate $E_M(x,0,0)$ in Eq. (39) over x and recover the model expression for the isoscalar magnetic moment [49]

$$\int_{-1}^{1}\mathrm{d}x\, E_M(x,0,0) = \frac{M_N N_c}{2I} \sum_{\substack{m,\mathrm{occ}\\ j,\mathrm{non}}} \frac{1}{E_j - E_m}\,\langle m|\tau^3|j\rangle\,\langle j|\,\gamma^0(\boldsymbol{\gamma}\times\hat{\mathbf{X}})^3\,|m\rangle = 3\mu^{(T=0)}\ . \tag{40}$$

---

[1] Of course, by limiting oneself to $\xi = 0$ one drops important physics. E.g., the skewedness parameter is related to the correlation length between partons, see [47] and references therein. The present calculation unfortunately cannot shed any light in this respect.

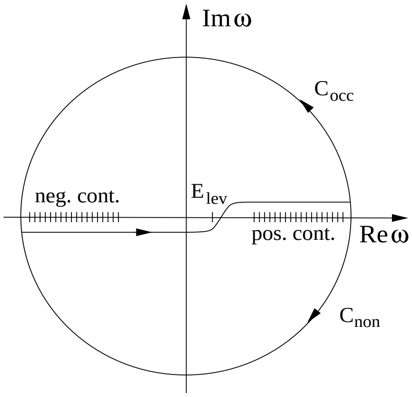

FIG. 1: The contour C of the ω-integral in Eq. (41).

VI. THE FORWARD LIMIT OF $(E^u + E^d)(x, \xi, t)$

In order to compute the forward limit $(E^u + E^d)(x, 0, 0) \equiv E_M(x, 0, 0) - (f_1^u + f_1^d)(x)$ we have to numerically evaluate the model expression (39) for $E_M(x, 0, 0)$. The distribution function $(f_1^u + f_1^d)(x)$ was already studied in [26, 28, 29]. The numerical methods needed for that were developed in Refs. [28–30] in the context of usual parton distributions functions in leading and subleading order of the large-N_c expansion. We restrict ourselves to the forward limit since this numerical technic does not allow a full calculation of GPDs for all values of ξ and t.

A. Gradient expansion and chiral enhancement of GPDs

Before studying the model expression (29) numerically in the model we shall consider the gradient expansion of $E_M(x, \xi, t)$. This expansion consists in expanding model expressions in powers of the gradients of the (static) chiral field ∇U. Such an expansion would quickly converge if the soliton field were slowly varying, i.e. if the soliton were large $\nabla U \sim 1/R_{\rm sol} \ll M$ where $R_{\rm sol}$ is the scale characterizing the soliton size. However, for the physical soliton solution $R_{\rm sol} \sim 1/M$. Nevertheless the gradient expansion is instructive and allows – among others – to study the UV-behaviour of the model expressions. Also as we shall see below the gradient expansion allows to obtain strong enhancement of GPD $E_M(x, \xi, t)$ in the region of small x. This enhancement is related to the effect of the pion cloud.

The model expression for $E_M(x, \xi, t)$ can be rewritten equivalently in the following way

$$
\begin{aligned}
E_M(x,\xi,t) &= \frac{N_c M_N^2 \epsilon^{3bc}\Delta^b}{2I\,\boldsymbol{\Delta}_\perp^2}\,\mathrm{tr}_{\gamma,F}\int_C \frac{\mathrm{d}\omega\mathrm{d}^3\mathbf{p}}{(2\pi)^4}\langle \mathbf{p}-\tfrac{\boldsymbol{\Delta}}{2}| \\
&\quad\times\Biggl[\delta(\omega+p^3-xM_N)(1+\gamma^0\gamma^3)\,\frac{1}{\omega-H}\,\tau^c\,\frac{1}{\omega-H} \\
&\quad+\frac{\partial}{\partial xM_N}\,\delta(\omega+p^3-xM_N)(1+\gamma^0\gamma^3)\tau^c\frac{1}{\omega-H}\Biggr]|\mathbf{p}+\tfrac{\boldsymbol{\Delta}}{2}\rangle
\end{aligned}
\tag{41}
$$

where “$\mathrm{tr}_{\gamma,F}$” denotes the trace over Dirac- and flavour indices. The contour C is defined in Fig. 1. Closing the contour C in the upper half of the complex ω-plane yields the expression in Eq. (29), closing it in the lower half plane one obtains the equivalent expression where the summation goes over non-occupied states m, cf. the sequence of Eq. (29).

Expanding the expression in Eq. (41) in powers of ∇U one obtains[2] already from the zeroth order in (∇U) the following result for the continuum contribution

$$
\begin{aligned}
E_M^{\rm cont}(x,\xi,t) &= \frac{M_N^2 f_\pi^2}{4I\,\boldsymbol{\Delta}_\perp^2}\int\frac{\mathrm{d}^3\mathbf{k}}{(2\pi)^3}f(\mathbf{k}+\tfrac{\boldsymbol{\Delta}}{2})f(\mathbf{k}-\tfrac{\boldsymbol{\Delta}}{2})\Bigl[-\boldsymbol{\Delta}^2\,k^3+\Delta^3(\boldsymbol{\Delta}\mathbf{k})\Bigr] \\
&\quad\times\left\{\frac{\Theta(xM_N+k^3)\Theta(\xi-x)-\Theta(-xM_N-k^3)\Theta(x-\xi)}{k^3-\xi M_N}+(\xi\leftrightarrow-\xi)\right.
\end{aligned}
$$

---

[2] For that we rewrite the operator $1/(\omega-H)=\frac{1}{2}(\omega+H)/(\omega^2-H^2)+\frac{1}{2}(\omega^2-H^2)^{-1}(\omega+H)$ where $H^2=\hat{\mathbf{p}}^2+M^2+iM\boldsymbol{\gamma}\boldsymbol{\nabla}U^{\gamma_5}$, and expand it in powers of $iM\boldsymbol{\gamma}\boldsymbol{\nabla}U^{\gamma_5}$. Such a “symmetric expansion” of $1/(\omega-H)$ ensures the hermiticity of the operator also in the case when the series in ∇U is truncated.

$$+\frac{\Theta(x-\xi)\Theta(-x-\xi)-\Theta(-x+\xi)\Theta(x+\xi)}{2\xi M_N}\Bigg\}+\mathcal{O}(\nabla U) \tag{42}$$

where $f(\mathbf{q})=f(|\mathbf{q}|)$ is one of the functions describing the Fourier transform of the $U(\mathbf{x})$-field

$$\int \mathrm{d}^3\mathbf{x}\,(U(\mathbf{x})-1)\,e^{-i\mathbf{q}\mathbf{x}} = g(\mathbf{q})+\frac{i\boldsymbol{\tau}\mathbf{q}}{|\mathbf{q}|}f(\mathbf{q})\ ; \quad f(\mathbf{q})\equiv 4\pi\int_0^\infty \mathrm{d}r\ r^2 j_1(r|\mathbf{q}|)\ \sin P(r)\ . \tag{43}$$

Note that the property $E_M(x,\xi,t)=E_M(x,-\xi,t)$ holds manifestly for the result in Eq. (42).

In the derivation of Eq. (42) we encountered a logarithmic UV-divergence proportional to M^2. This UV-divergence can be regularized, e.g., by means of a Pauli-Villars subtraction as

$$E_M^{\rm cont}(x,\xi,t)_{\rm reg}=E_M^{\rm cont}(x,\xi,t;M)-\frac{M^2}{M_{\rm PV}^2}E_M^{\rm cont}(x,\xi,t;M_{\rm PV}). \tag{44}$$

We removed the dependence of the result on cutoff and regularization scheme in favour of a physical parameter, namely the pion decay constant $f_\pi=93\,\mathrm{MeV}$ given in the effective theory (10) by the (Euclidean loop) integral

$$f_\pi^2=\int\frac{\mathrm{d}^4p_E}{(2\pi)^4}\,\frac{4N_cM^2}{(p_E^2+M^2)^2}\Bigg|_{\rm reg} \tag{45}$$

which exhibits a similar UV-behaviour and can be regularized analogously. In the first order of the gradient expansion, indicated only symbolically as $\mathcal{O}(\nabla U)$ in Eq. (42), we also encounter a logarithmic divergence which can be removed by means of (44). Still higher orders in the gradient expansion yield finite results – as one can conclude from dimensional counting. (Or from the fact that the isoscalar magnetic moment appears at the order $(\nabla U)^2$ and is UV-finite, cf. Ref. [23].)

Eq. (42) may give at best only a rough estimate for $E_M(x,\xi,t)$. Nevertheless it contains already main features of the total result. Apart from the UV-properties, which we discussed above, the small x-behaviour in the chiral limit is of interest since the exact numerical calculation is performed under such conditions. The soliton profile behaves at large distances as

$$P(r)=-\frac{B}{r^2}\,(1+m_\pi r)\,\exp(-m_\pi r)\ ,\quad B=\frac{3\,g_A^{(3)}}{8\pi\,f_\pi^2}\quad\text{for } r\gg\sqrt{B} \tag{46}$$

with B related to axial isovector coupling constant $g_A^{(3)}=1.26$ by means of equations of motion. The large distance behaviour (46) of the soliton profile translates into the infrared-behaviour of the function $f(\mathbf{q})$ as

$$f(\mathbf{q})=-\,\frac{3\,g_A^{(3)}}{2f_\pi^2}\,\frac{1}{\mathbf{q}^2+m_\pi^2}\quad\text{for small }\mathbf{q}^2,m_\pi^2\ll B^{-1}. \tag{47}$$

Note that $B^{-1}<(4\pi\,f_\pi)^2\sim 1\,\mathrm{GeV}^2$ which is a typical scale for chiral symmetry breaking effects. Apparently the limits $m_\pi\to 0$ and $\mathbf{q}\to 0$ do not commute.[3] In the forward limit in Eq. (42) this means

$$E_M(x,0,0)=\frac{M_N^2f_\pi^2}{6I(2\pi)^2}\int\limits_{|xM_N|}^{\infty}\mathrm{d}q\,q^2f(q)^2\left(1-\frac{|xM_N|}{q}\right)\overset{x\to 0}{=}\left[\frac{3g_A^{(3)}}{8\pi f_\pi}\right]^2\frac{M_N}{I}\cdot\begin{cases}\dfrac{1}{x} & \text{for } m_\pi=0,\\[2ex] \dfrac{\pi}{2}\,\dfrac{M_N}{m_\pi} & \text{for } m_\pi\neq 0.\end{cases} \tag{48}$$

Note that the soliton moment of inertia could be eliminated in favour of the Δ-nucleon mass-splitting as $M_\Delta-M_N=3/(2I)$.

Although derived in the leading order of the gradient expansion of model expressions Eq. (48) is of more general nature as it is related to the effect of pion cloud. Therefore it is should be possible to derive the above expression by means of chiral perturbation theory. Another interesting question is to find phenomenological manifestations of the chiral enhancement. This would open new exciting possibilities to investigate chiral symmetry breaking in the hard exclusive processes.

---

[3] The non-commutativity of such limits is known, e.g., from studies of the polarized photon structure function, where the virtuality of the photon plays the role of the momentum $\mathbf{q}$. In that case it is known that the correct order of limits is to take first the photon virtuality to zero, and only then to consider $m_\pi\to 0$ [50]. However, in our context it is not clear in which order the limits should be taken, though phenomenology may suggest first to keep m_π finite.

B. Numerical calculation

As any quantity in the model, $E_M(x,0,0)$ is composed of a contribution of the discrete level and of the continuum contribution defined, respectively, as

$$\begin{aligned}
E_M^{\rm lev}(x,0,0) &= \frac{M_N^2 N_c}{4I}\,\epsilon^{3jk}\sum_{\substack{E_j,{\rm all}\\ j\neq{\rm lev}}}\left[\frac{2}{E_j-E_{\rm lev}}-\frac{\partial}{\partial xM_N}\right]\langle{\rm lev}|\tau^k|j\rangle\,\langle j|\,(1+\gamma^0\gamma^3)\,\delta(xM_N-E_m-\hat p^3)\,\hat X_\perp^j\,|{\rm lev}\rangle\\
E_M^{\rm cont}(x,0,0) &= \frac{M_N^2 N_c}{4I}\,\epsilon^{3jk}\sum_{\substack{E_m<0\\ E_j,{\rm all}\\ m\neq j}}\left[\frac{2}{E_j-E_m}-\frac{\partial}{\partial xM_N}\right]\langle m|\tau^k|j\rangle\,\langle j|\,(1+\gamma^0\gamma^3)\,\delta(xM_N-E_m-\hat p^3)\,\hat X_\perp^j\,|m\rangle\\
&= -\frac{M_N^2 N_c}{4I}\,\epsilon^{3jk}\sum_{\substack{E_m>0\\ E_j,{\rm all}\\ m\neq j}}\left[\frac{2}{E_j-E_m}-\frac{\partial}{\partial xM_N}\right]\langle m|\tau^k|j\rangle\,\langle j|\,(1+\gamma^0\gamma^3)\,\delta(xM_N-E_m-\hat p^3)\,\hat X_\perp^j\,|m\rangle
\end{aligned} \tag{49}$$

For a constant (momentum-independent) M the continuum contribution to $E_M(x,\xi,t)$ is UV-divergent. It can be regularized by means of a single Pauli-Villars according to Eq. (44). In the context of parton distribution functions the Pauli-Villars method is the preferred regularization scheme because it preserves fundamental properties of parton distributions such as sum rules, positivity, etc. [26]. It should be noted that the contribution of the discrete level, which is always finite, must not be regularized [29].

The numerical method to evaluate $E_M(x,0,0)$ consists in placing the soliton in a large but finite spherical box, introducing free basis states (eigenstates of the free Hamiltonian, see Eq. (11) and below), and discretizing the basis by imposing appropriate boundary conditions following Kahana and Ripka [48]. The full Hamiltonian (11) can be diagonalized numerically in this basis [49]. With the eigenfunctions and eigenstates, $\Phi_n(\mathbf{x})$ and E_n, one is then in a position to evaluate Eq. (49). This is most conveniently done by converting the model expression (49) into a spherically symmetric form [28]. For that we introduce in (49) a unit vector $\mathbf{a}$ such that the original expression is recovered for $\mathbf{a}=\mathbf{e}^{(3)}$,

$$\epsilon^{3jk}(1+\gamma^0\gamma^3)\,\delta(xM_N-E_m-\hat p^3)\,\hat X_\perp^j \to (1+\gamma^0\mathbf{a}\cdot\boldsymbol{\gamma})\,\delta(xM_N-E_m-\mathbf{a}\cdot\hat{\mathbf{p}})\,(\mathbf{a}\times\hat{\mathbf{X}})^k\;. \tag{50}$$

Then we average over all possible orientations of the vector $\mathbf{a}$. This yields

$$\begin{aligned}
E_M(x,0,0) \;&=\; -\frac{M_N^2 N_c}{4I}\sum_{\substack{m,{\rm occ}\\ j,{\rm all}\\ m\neq j}}\left[\frac{2}{E_m-E_j}+\frac{\partial}{\partial xM_N}\right]\langle m|\tau^k|j\rangle\,\langle j|\Biggl[(\hat{\mathbf{p}}\times\hat{\mathbf{X}})^k\,\frac{I_1(|\hat{\mathbf{p}}|,E_m,x)}{|\hat{\mathbf{p}}|^2}\\
&\quad+(\gamma^0\boldsymbol{\gamma}\times\hat{\mathbf{X}})^k\,\frac{(I_0-I_2)(|\hat{\mathbf{p}}|,E_m,x)}{2|\hat{\mathbf{p}}|}+(\hat{\mathbf{p}}\times\hat{\mathbf{X}})^k\,(\gamma^0\boldsymbol{\gamma}\cdot\hat{\mathbf{p}})\,\frac{(3I_2-I_0)(|\hat{\mathbf{p}}|,E_m,x)}{2|\hat{\mathbf{p}}|^3}\Biggr]|m\rangle\;,\\
&\quad\text{where}\quad I_l(|\hat{\mathbf{p}}|)=\frac{(xM_N-E_m)^l}{2\,|\hat{\mathbf{p}}|^l}\,\Theta(|\hat{\mathbf{p}}|-|xM_N-E_m|)\;.
\end{aligned} \tag{51}$$

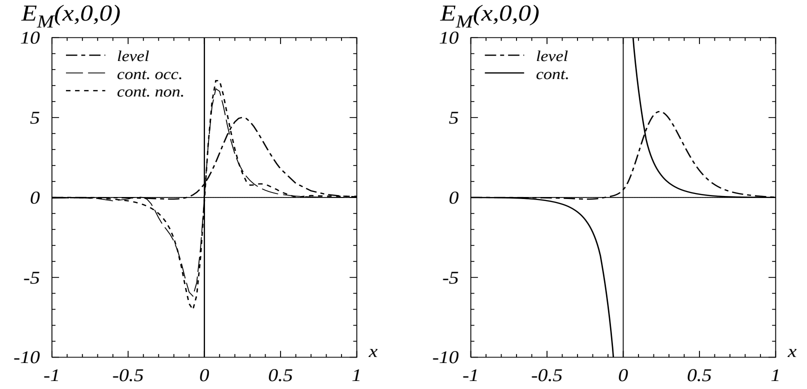
Although non-commuting operators appear in (51) nevertheless the final result is a hermitian operator. The averaging procedure must, of course, preserve hermiticity. It is this step which prevents us from tackling also the problem to compute numerically $E_M(x,\xi,t)$ for non-zero ξ and t. For finite $\boldsymbol{\Delta}$ the appearance of an additional direction, namely along $\boldsymbol{\Delta}_\perp$ perpendicular to the 3-direction, makes the resulting expressions unsuitable for a numerical evaluation.

Since we work with a discrete basis, the Θ-functions in (51) would lead to discontinuous functions. Therefore we convolute the true (but due to finite size effects discontinuous) function with a narrow Gaussian

$$E_M^{sm}(x,0,0)=\frac{1}{\sqrt{\pi}\gamma}\int\limits_{-\infty}^{\infty}{\rm d}x'\;e^{-(x-x')^2/\gamma^2}\;E_M(x',0,0)\;. \tag{52}$$

The width γ has to be chosen adequately according to the spacing of the discrete basis states [28]. The effect of smearing can be removed by a deconvolution at the end of the calculation.

Fig. 2a shows the level and continuum contribution to $E_M(x,0,0)$ computed with $M=350\,\text{MeV}$ in a box of the size $D_{\rm box}=18\,\text{fm}$ with $\gamma=0.08$. The continuum contribution is evaluated in the two equivalent ways, Eq. (49). This explicit check of the equivalence of summations over respectively occupied and non-occupied states is an important check of the numerical method, and provides a measure for the numerical accuracy. As can be seen from Fig. 2a the two calculations yield the same result within few percent.



a **b**

FIG. 2: $E_M(x,0,0) = (E^u + E^d + H^u + H^d)(x,0,0)$ as function of x from the χQSM at a low scale of about $\mu \approx 600\,\mathrm{MeV}$. At negative x the curves show minus the antiquark distributions. Fig. 2a shows the (smeared) discrete level and continuum contribution. The latter is evaluated in the two equivalent ways in Eq. (49), namely by summing respectively over occupied and non-occupied states. In Fig. 2b the effect of the Gaussian smearing is removed. These are the final results for respectively the discrete level and the continuum contribution to $E_M(x,0,0)$.

We observe that the equivalence is spoiled by unphysical boundary effects in the chiral limit, when the soliton profile $P(r) \propto 1/r^2$ at large distances. In order to restore the equivalence it is necessary that the profile decays faster at large r, e.g., as $P(r) \propto \exp(-m'_\pi r)(1 + m'_\pi r)/r^2$ (the numerical parameter m'_π is not to be confused with the physical pion mass discussed above). Since the issue of computing self-consistent profiles with finite pion masses in the Pauli-Villars regularization is not yet solved, cf. [51] for a discussion, we use the chiral self-consistent profile computed in [29] up to some r_A and continue it for $r > r_A$ with an artificial Yukawa-tail-like suppression of the above kind. We find the results practically independent of r_A and m'_π in the range $r_A = (4-8)\,\mathrm{fm}$ and $m'_\pi = (100-200)\,\mathrm{MeV}$. This proves that what matters in this context is only a sufficiently small value of the profile at the boundary $r = D_{\rm box}$, and makes the the extrapolations $r_A \to \infty$ and/or $m'_\pi \to 0$ superfluous, which in principle would be necessary to remove any dependence of these numerical parameters. The equivalence demonstrated in Fig. 2a is achieved in this way. This procedure was applied successfully to cure an analogue problem in the calculation of the transversity distribution [34].

Let us comment on the effect of smearing, which is negligible whenever one deals with a continuous function such as the contribution of the discrete level, cf. Fig. 2a and 2b. However, in the case of the continuum contribution the smearing "hides" an $1/x$ singularity which becomes apparent only in the final result after the smearing is removed. This is done by Fourier transforming $E_M^{sm}(x,0,0)$ of Eq. (52), dividing out the smearing Gaussian, and re-Fourier transforming – which yields the final results shown in Fig. 2b.

We remark that in the χQSM the parton distribution functions (and forward limits of GPDs) do not vanish for $|x| \geq 1$. Instead they decay as $\exp(-\mathrm{const}\, N_c x)$ at $|x| \geq 1$ [26] which is, in fact, numerically very small even for $N_c = 3$.

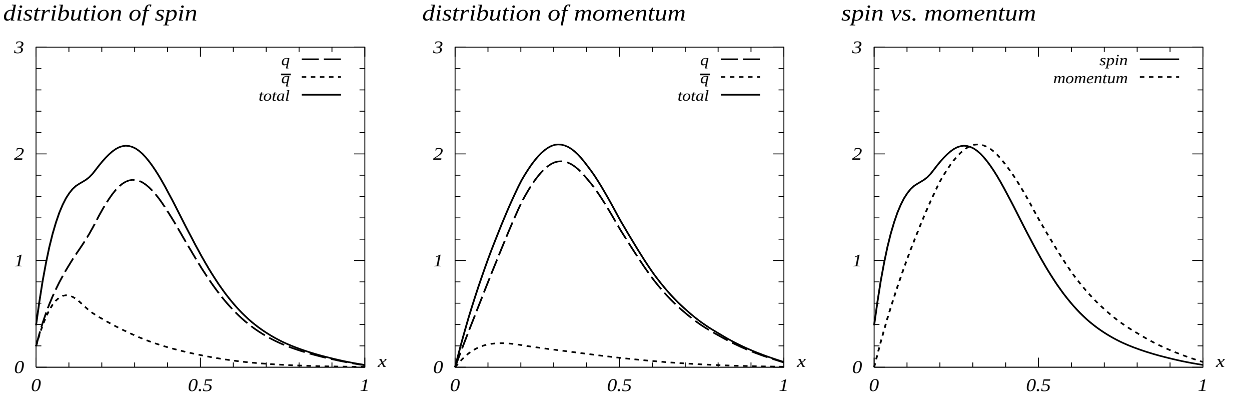
C. Discussion of the results

We observe in $E_M(x,0,0)$ that the discrete level contributes predominantly to the distribution of quarks rather than antiquarks. The continuum, however, contributes nearly equal portions to quark and antiquark distributions. As a result the isoscalar magnetic moment receives a negligible contribution from the continuum. This strong dominance of the level contribution in the isoscalar magnetic moment was observed in earlier calculations [24]. The result (in units of the nuclear magneton)

$$\mu^{(T=0)} \equiv (\mu^p + \mu^n) = \frac{1}{3}\int_{-1}^{1}\mathrm{d}x\; E_M(x,0,0) = 0.65 \quad \text{vs.} \quad 0.88_{\rm exp}\;, \tag{53}$$

agrees with the experimental value to within 25%, i.e. to within an accuracy typical for χQSM results [25].

We can interpret $xE_M(x,0,0) \equiv x(H^u + H^d + E^u + E^d)(x,0,0)$ (and analog for antiquarks) as the distribution of spin in the nucleon in the following sense. This quantity tells us how much of the nucleon spin is due to quarks (and antiquarks) from which region in x. In Fig. 3a we see that the contribution due to quarks is concentrated around $x \approx 0.3$, while the contribution of antiquarks has its maximum in the region $x \approx 0.1$. It is worthwhile stressing that a sizeable fraction of the nucleon spin is due to antiquarks already a the low scale of the model. We find the nucleon spin distributed among antiquarks and quarks as antiquarks : quarks = 1 : 4. Integrating $xE_M(x,0,0)$ over



a **b** **c**

FIG. 3: Comparison of the "spin" and "momentum distribution" in the nucleon in the χQSM at a low scale of about $\mu = 600\,\mathrm{MeV}$. Fig. 3a shows the respective contributions of quarks and antiquarks to the nucleon spin as distributions in x, defined as $xE_M(x,0,0) = x(E^u+E^d+H^u+H^d)(x,0,0)$ (and analog for antiquarks). The sum of the integrals over x of the quark and antiquark contributions yields $2J^Q = 1$. Fig. 3b shows the distribution of the momentum in the nucleon, $x(f_1^u+f_1^d)(x)$, for quarks (and analog for antiquarks). The sum of the integrals over x of the quark and antiquark contributions yields $M^Q = 1$. In Fig.2c the total spin and momentum distributions are compared.

x and summing up the contributions of quarks and antiquarks we obtain unity (within 2% numerical accuracy) – in agreement with the spin sum rule in the model, Eq. (33).

It is instructive to compare – within the model – the spin distribution to the momentum distribution of quarks and antiquarks in the nucleon. First we note that antiquarks are sizeable also in the momentum distribution, however, less pronounced than in the case of the spin distribution, see Fig. 3b. The nucleon momentum is distributed as antiquarks : quarks $\approx 1:10$. Parameterizations performed at comparably low scales [52] indicate that about 30% of the nucleon momentum is carried by gluons already at low scales. Thus, the distribution of momentum in the model seems to overestimate the contribution of the quarks and antiquarks by about 30%, which is within the expected accuracy of the model [31]. It will be interesting to see whether the situation is similar in the case of the spin distribution.

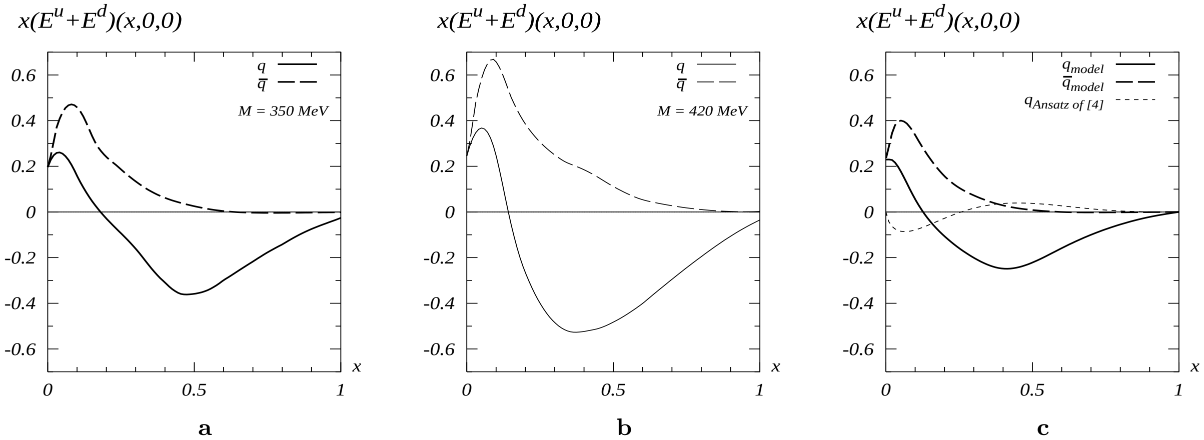
Finally, comparing the momentum and spin distributions, Fig. 3c, we observe that the spin distribution is somehow softer, i.e. shifted towards smaller x.

In Fig. 4a, we present the final results for $x(E^u+E^d)(x,0,0)$ and $x(E^{\bar{u}}+E^{\bar{d}})(x,0,0)$. We observe that $x(E^u+E^d)(x,0,0)$ is positive at small x, changes sign at $x \approx 0.18$, and is sizeable and negative at large x, taking its maximum around $x \approx 0.5$. In contrast, $x(E^{\bar{u}}+E^{\bar{d}})(x,0,0)$ appears everywhere positive and rather large at smaller values of x. For the second moment of $(E^u+E^d)(x,0,0)$ we obtain zero (within numerical accuracy) and confirm numerically the sum rule in Eq. (34), which – let us stress it – must be fulfilled in any model which lacks explicit gluon degrees of freedom but describes the nucleon consistently in terms of quark- and antiquark degrees of freedom.

In our calculation $x(E^u+E^d)(x,0,0)$ results from the cancellation of two much larger quantities, namely $xE_M(x,0,0)$ and $x(f_1^u+f_1^d)(x)$, see Figs. 3 and 4, such that one could worry whether a small change in parameters could lead to a much different final result. The only parameter, which could be in principle varied[4], is the constituent quark mass M. A calculation with $M = 420\,\mathrm{MeV}$ yields a somehow larger result, see Fig. 4b. However, what is more important in our context, it fully confirms the basic features of the calculation with $M = 350\,\mathrm{MeV}$ in Fig. 4a, which is our final result. Fig. 4c shows the model results LO-evolved [58] to $Q^2 = 5\,\mathrm{GeV}^2$ which is a typical scale in experiments. Hereby we assume the gluon GPD $E^g(x,0,0)$, which mixes with $(E^u+E^d+E^{\bar{u}}+E^{\bar{d}})(x,0,0)$ under evolution, to be zero at the initial scale taken to be $\mu^2 = 0.36\,\mathrm{GeV}^2$. This is justified by the instanton vacuum model, where twist-2 gluon distributions appear suppressed with respect to the respective quark distributions. (The meaning of the dotted line in Fig. 4c is explained in the next section.)

---

[4] We work here with the value $M = 350\,\mathrm{MeV}$ which follows from instanton phenomenology [37, 38] and was used in calculations of parton distributions and GPDs [15–17, 26–33]. However, in numerous model calculations M was allowed to vary in the range $(350-450)\,\mathrm{MeV}$ [25]. The value $M = 420\,\mathrm{MeV}$ was somehow preferred because it reproduced exactly the delta-nucleon mass-splitting within the proper-time regularization [25].



a **b** **c**

FIG. 4: Fig. 4a shows the final result for $x(E^u + E^d)(x,0,0)$ and $x(E^{\bar{u}} + E^{\bar{d}})(x,0,0)$. For sake of comparison, see text, Fig. 4b shows the result one obtains with a constituent mass $M = 420\,\mathrm{MeV}$. Fig. 4c shows the final model result (Fig. 4a) LO-evolved from the initial scale taken as $\mu^2 = 0.36\,\mathrm{GeV}^2$ to the scale $Q^2 = 5\,\mathrm{GeV}^2$ typical in experiments. For comparison the Ansatz of Ref. [4] is shown for quarks (dotted line). The corresponding antiquark distribution was assumed to be zero in Ref. [4]. Note that the effect of sea quarks was simulated in [4] by a δ-function not visible in the plot.

VII. PHENOMENOLOGICAL IMPLICATIONS

Azimuthal asymmetries in hard exclusive production of vector mesons or pion pairs from a transversely polarized target are among the observables which are most sensitive to $E^a(x,\xi,t)$ [4]. Let us define

$$A_M(x_B,t,Q^2) = \frac{1}{|S_\perp|}\frac{\int_0^\pi \mathrm{d}\phi\;\sigma(\phi) - \int_\pi^{2\pi}\mathrm{d}\phi\;\sigma(\phi)}{\int_0^{2\pi}\mathrm{d}\phi\;\sigma(\phi)}, \tag{54}$$

where σ is the cross section for the process $\gamma_L^*(q) + P(p) \to M + P(p')$ with $\gamma_L^*(q)$ denoting the deeply virtual longitudinally polarized photon with momentum q. P is the incoming (outgoing) proton with momentum $p\,(p')$, and M denotes the produced longitudinally polarized vector meson or the pion pair. For notational simplicity we omit to indicate that σ is differential in $t = (P-P')^2$, $Q^2 = -q^2$, $x_B = Q^2/(2Pq)$ which is related to the skewedness parameter as $x_B = 2\xi/(1+\xi)$ in the limit $Q^2 \to \infty$, and the angle ϕ between the transverse proton spin $S_\perp$ and the plane spanned by the virtual photon and the produced meson.

For not too small x_B the gluon exchange mechanism can be neglected in a first approximation and the asymmetry A_M reads [4, 53]

$$A_M = -\frac{2|\Delta_\perp|}{\pi M_N}\,\frac{\mathrm{Im}(B^*C)}{|B|^2(1-\xi^2) - |C|^2(\xi^2 + \frac{t}{4M_N^2}) - \mathrm{Re}(BC^*)2\xi^2} \tag{55}$$

where B and C are given for the respective final state M by

$$\begin{aligned}
B_{\rho^0} &= \int_{-1}^{1}\mathrm{d}x\;(e_uH^u - e_dH^d)\left(\frac{1}{x-\xi+i\varepsilon} + \frac{1}{x+\xi-i\varepsilon}\right)\\
C_{\rho^0} &= \int_{-1}^{1}\mathrm{d}x\;(e_uE^u - e_dE^d)\left(\frac{1}{x-\xi+i\varepsilon} + \frac{1}{x+\xi-i\varepsilon}\right)\\
B_{\omega} &= \int_{-1}^{1}\mathrm{d}x\;(e_uH^u + e_dH^d)\left(\frac{1}{x-\xi+i\varepsilon} + \frac{1}{x+\xi-i\varepsilon}\right)\\
C_{\omega} &= \int_{-1}^{1}\mathrm{d}x\;(e_uE^u + e_dE^d)\left(\frac{1}{x-\xi+i\varepsilon} + \frac{1}{x+\xi-i\varepsilon}\right)\\
B_{\pi^0\pi^0} &= \int_{-1}^{1}\mathrm{d}x\;(e_uH^u + e_dH^d)\left(\frac{1}{x-\xi+i\varepsilon} - \frac{1}{x+\xi-i\varepsilon}\right)\\
C_{\pi^0\pi^0} &= \int_{-1}^{1}\mathrm{d}x\;(e_uE^u + e_dE^d)\left(\frac{1}{x-\xi+i\varepsilon} - \frac{1}{x+\xi-i\varepsilon}\right)\,.
\end{aligned} \tag{56}$$

An advantage of choosing such target spin asymmetries to access GPDs is that the (poorly known) meson distribution amplitudes cancel out.

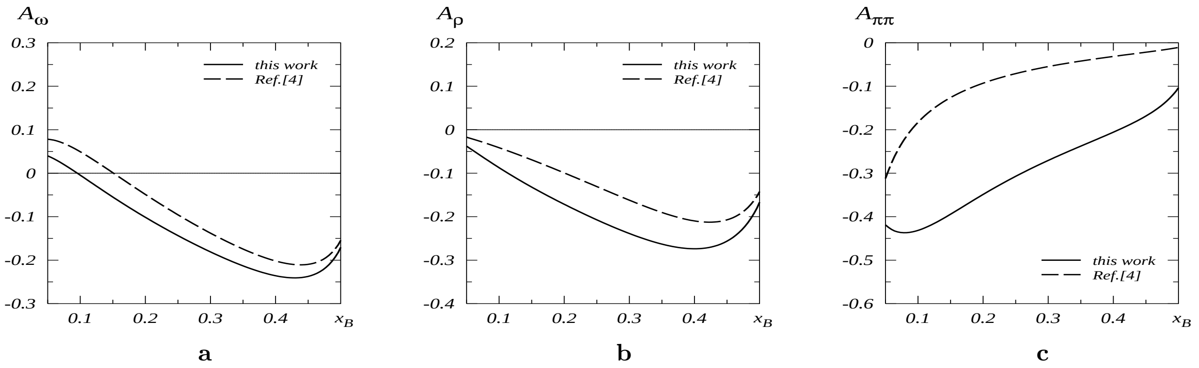


FIG. 5: The transverse spin asymmetry in hard exclusive production of (a) ω^0, (b) ρ^0, and (c) a π^0 pair as functions of x_B at $t = -0.5$ GeV^2 and $Q^2 = 5$ GeV^2.

As we computed here only the forward limit and are particularly interested to see the impact of our result in comparison to what previously was discussed in literature, we shall use the method of Ref. [54] to generate ξ- and t-dependence from a given forward limit according to

$$E^q(x,\xi,t) = E^q_{DD}(x,\xi)\; F^q_2(t) - \text{D-term} \tag{57}$$

with the D-term as predicted in the model [4], $F_2(t)$ from [55, 56] and the so-called double distribution given by

$$E^q_{DD}(x,\xi) = \int_{-1}^{1} \mathrm{d}\beta \int_{-1+|\beta|}^{1-|\beta|} \mathrm{d}\alpha\; \delta(x-\beta-\alpha\xi)\, E^q(\beta,0,0)\, h(\beta,\alpha)\;. \tag{58}$$

The Ansatz (57, 58) satisfies the polynomiality condition (4) for any "profile function" $h(\beta,\alpha)$, e.g., for

$$h(\beta,\alpha) = \frac{\Gamma(2b+2)}{2^{2b+1}\Gamma^2(b+1)} \frac{\left[(1-|\beta|)^2-\alpha^2\right]^b}{(1-|\beta|)^{2b+1}} \tag{59}$$

where we shall choose $b = 1$ for our analysis, cf. Ref. [4]. For $(E^u + E^d)(x,0,0)$ we use the result obtained in this work, LO-evolved[5] [58] to $Q^2 = 5$ GeV^2, cf. Fig. 4c. For $(E^u - E^d)(x,0,0)$ we shall employ the Ansatz

$$(E^u - E^d)(x,0,0) = c_1(f^u_{1\mathrm{val}} - f^d_{1\mathrm{val}})(x) + c_2\delta(x) \tag{60}$$

inspired by the model results for $(E^u - E^d)(x,0,0)$ [4]. In Eq. (60) $f^q_{1\mathrm{val}}$ denotes the respective valence quark distribution. The parameters $c_{1,2}$ are fixed from $\kappa^u - \kappa^d = 3.706$ and, in order to discuss everything in terms of results from the model, $J^u - J^d \approx 0.2$ found in the χQSM [4].

We shall compare the results obtained with this Ansatz, which is consistently based on predictions from the χQSM to the results presented in Ref. [4] where, in lack of better knowledge, the Ansatz (60) was assumed to hold also in the flavour singlet case. Such an assumption is, however, not supported by our direct calculation as it is demonstrated in Fig. 4c.

The GPD $H^q(x,\xi,t)$ is modeled in an analog way on the basis of the parameterization [59] for $f^q_1(x)$ as described in Ref. [4].

As can be seen from Fig. 5 the asymmetry has little sensitivity to the Ansatz used for $(E^u + E^d)(x,0,0)$ in the case of ω^0 or ρ^0 production. We find that the process most sensitive to $(E^u + E^d)(x,0,0)$ is the production of a π^0 pair. The effect of different Ansätze can cleanly be distinguished. Experiments at HERMES or JLAB could provide interesting insights. However, for an unambiguous quantitative analysis of the data it will be necessary to consider systematically power and NLO corrections.

---

[5] One could also first construct the GPD at the low scale in the above describe way, and then evolve it to the relevant scale. The difference due to the non-commutativity of these steps is, however, small [57] – far smaller than other uncertainties in our model calculation as well as corrections due to the neglect of NLO-corrections, possible power corrections, etc. We shall neglect it here.

VIII. SUMMARY AND CONCLUSIONS

We have presented in the framework of the flavour-SU(2) version of the chiral quark-soliton model a study of unpolarized GPDs, which appear at subleading order in the large-N_c limit, namely the flavour combinations $(E^u + E^d)(x,\xi,t)$ and $(H^u - H^d)(x,\xi,t)$. For that we generalized the methods of Ref. [15] developed to study the leading large-N_c GPDs, i.e. the respectively opposite flavour combinations.

Interestingly, the GPDs $(H^u + H^d)(x,\xi,t)$ and $(E^u + E^d)(x,\xi,t)$ are of the same order in the large-N_c counting but handled differently in the model. The former appears already in leading order, while for the latter one must invoke $1/N_c$ (rotational) corrections to obtain a non-vanishing result. Nevertheless they enter the spin sum rule on equal footing, which is satisfied in the model as we demonstrated. Furthermore, we have shown that also the subleading GPDs satisfy the polynomiality condition, and that the coefficients in front of the highest power in ξ in even moments of $(H^u + H^d)(x,\xi,t)$ and $(E^u + E^d)(x,\xi,t)$ are equal to each other up to an opposite sign. Given the different technical handling in the model, the fulfillment of general requirements where both GPDs are involved is a strong check of the consistency of the approach.

In the chiral quark-soliton model $M^Q = 2J^Q$ already at a low scale, i.e. the fractions of nucleon momentum and spin carried by quarks and antiquarks are the same. In QCD this relation becomes exact in the limit of a large renormalization scale. Actually this is not a specific prediction of the chiral quark-soliton model, but should hold in any model describing the nucleon consistently in terms of quark and antiquark degrees of freedom, i.e. without gluon degrees of freedom. For such models to be consistent $M^Q = 2J^Q = 1$ must hold. The chiral quark-soliton model fulfills this requirement. In the framework of the χQSM the contribution of gluons to the nucleon momentum and angular momentum is suppressed with respect to the corresponding quark contributions by the small parameter characterizing the packing fraction of instantons in vacuum [40].

We then focused on the GPD $(E^u + E^d)(x,\xi,t)$ and computed numerically its forward limit with a constant (momentum-independent) constituent quark mass M using the Pauli-Villars regularization. We found that $(E^u + E^d)(x,0,0)$ is negative at larger x and sizeable, and positive at small x, changing the sign at $x \approx 0.2$, while $(E^{\bar{u}} + E^{\bar{d}})(x,0,0)$ is always positive and concentrated towards smaller x. Noteworthy is that in the model in the chiral limit $(E^u + E^d)(x,0,0)$ is strongly enhanced at small x with respect to $(H^u + H^d)(x,0,0)$. It would be interesting to study in more detail the chiral mechanism responsible for that.

On the basis of our results we estimated azimuthal asymmetries in hard exclusive production of vector mesons and pion pairs from a transversely polarized proton target. We observe that pion pair production is very sensitive to $(E^u + E^d)(x,\xi,t)$. Data from experiments at HERMES or JLAB on this reaction would be well suited to distinguish among different models.

Our work – in particular the demonstration of the consistency of the approach – not only increases the faith into the applicability of the chiral quark-soliton model to the computation of GPDs, but also practically paves the way to further studies of GPDs in leading and subleading order of the large-N_c limit.

Acknowledgments

We thank Vadim Guzey for help on evolution, and thank Markus Diehl and Peter Kroll for valuable discussions. This work is partially supported by the Graduierten-Kolleg Bochum-Dortmund and Verbundforschung of BMBF. A Portuguese-German collaboration grant by GRICES and DAAD is acknowledged. M. V. P. thanks the Alexander von Humboldt-Stiftung for support by the Sofia Kovalevskaya-Award, FNRS (Belgium) and IISN.

Note added in proof

After this work was finished Ref. [60] appeared, where among others a fit of $(E^q - E^{\bar{q}})(x,0,t)$ to the Pauli form factor was reported. The result of Ref. [60] for $(E^u + E^d - E^{\bar{u}} - E^{\bar{d}})(x,0,0)$ is qualitatively similar to the ansatz of Ref. [4] plotted in Fig. 4c and differs from our result which is negative at all x.

APPENDIX A: MODEL SYMMETRIES

The effective Hamiltonian $\hat{H}_{\rm eff}$, Eq. (11), commutes with the parity operator $\hat{\Pi}$ and the grand-spin operator

$$\hat{\mathbf{K}} = \hat{\mathbf{S}} + \hat{\mathbf{L}} + \hat{\mathbf{T}} \tag{A1}$$

where $\hat{\mathbf{S}} = \frac{1}{2}\gamma_5\gamma^0\boldsymbol{\gamma}$, $\hat{\mathbf{L}} = \hat{\mathbf{r}} \times \hat{\mathbf{p}}$ and $\hat{\mathbf{T}} = \frac{1}{2}\boldsymbol{\tau}$ denote the single-quark spin, angular momentum and isospin operators, respectively. Thus, the single-quark states are characterized by the eigenvalues of $\hat{\Pi}$, $\hat{K}^2$ and K^3 as $|n\rangle = |E_n, \pi, K, K^3\rangle$.

Consider the unitary matrix G_5 given in the standard representation of Dirac- and flavour SU(2) matrices by $G_5 \equiv \gamma^2\gamma^5\tau^2$. It acts as $G_5\gamma^\mu G_5^{-1} = (\gamma^\mu)^T$ and $G_5\tau^a G_5^{-1} = -(\tau^a)^T$ such that in coordinate space the Hamiltonian (11) is transformed as $G_5 H G_5^{-1} = H^T$. This transformation acts as $G_5\Phi_n(\mathbf{x}) = \Phi_n^*(\mathbf{x})$. The G_5 transformation in the effective chiral theory corresponds to time reversal transformation accompanied by a flavour rotation [61]. Using the G_5-transformation one finds $\langle m|\tau^a|j\rangle = -\langle j|\tau^a|m\rangle$ and, e.g.,

$$\begin{aligned}
\langle m|(1+\gamma^0\gamma^3)F(\hat{\mathbf{p}})G(\hat{\mathbf{X}})H(\hat{\mathbf{p}})|j\rangle &= \langle j|(1-\gamma^0\gamma^3)H(-\hat{\mathbf{p}})G(\hat{\mathbf{X}})F(-\hat{\mathbf{p}})|m\rangle \\
\langle m|\tau^c(1+\gamma^0\gamma^3)F(\hat{\mathbf{p}})G(\hat{\mathbf{X}})H(\hat{\mathbf{p}})|j\rangle &= -\langle j|\tau^c(1-\gamma^0\gamma^3)H(-\hat{\mathbf{p}})G(\hat{\mathbf{X}})F(-\hat{\mathbf{p}})|m\rangle\,. \qquad \text{(A2)}
\end{aligned}$$

Another useful symmetry of the model is parity $\hat{\Pi}|m\rangle = p_m|m\rangle$ with $p_m = \pm 1$ depending on the parity of the state. We obtain, e.g.,

$$\langle m|\tau^c(1+\gamma^0\gamma^3)F(\hat{\mathbf{p}})G(\hat{\mathbf{X}})H(\hat{\mathbf{p}})|j\rangle = p_m p_j \langle m|\tau^c(1-\gamma^0\gamma^3)H(-\hat{\mathbf{p}})G(-\hat{\mathbf{X}})F(-\hat{\mathbf{p}})|j\rangle\,. \qquad \text{(A3)}$$

APPENDIX B: POLYNOMIALITY

For the discussion of moments the following expressions for $H_E(x,\xi,t)$ and $E_M(x,\xi,t)$ are more convenient

$$\begin{aligned}
H_E(x,\xi,t) = -\frac{M_N N_c}{12I}\int\frac{\mathrm{d}z^0}{2\pi}\,e^{iz^0 x M_N}\Biggl[\Biggl\{\sum_{\substack{m,\mathrm{occ}\\ j,\mathrm{all}}} e^{-iz^0E_m} - \sum_{\substack{m,\mathrm{all}\\ j,\mathrm{occ}}} e^{-iz^0E_j}\Biggr\}\frac{1}{E_m-E_j} \\
\times \langle m|\tau^a|j\rangle\,\langle j|\,\tau^a(1+\gamma^0\gamma^3)\,\exp(-iz^0\hat{p}^3/2)\,\exp(i\boldsymbol{\Delta}\hat{\mathbf{X}})\,\exp(-iz^0\hat{p}^3/2)\,|m\rangle \\
+iz^0\sum_{m,\mathrm{occ}} e^{-iz^0E_m}\langle m|3(1+\gamma^0\gamma^3)\,\exp(-iz^0\hat{p}^3/2)\,\exp(i\boldsymbol{\Delta}\hat{\mathbf{X}})\,\exp(-iz^0\hat{p}^3/2)\,|m\rangle\Biggr]\,, \qquad \text{(B1)}
\end{aligned}$$

$$\begin{aligned}
E_M(x,\xi,t) = \frac{iM_N^2 N_c}{2I}\int\frac{\mathrm{d}z^0}{2\pi}\,e^{iz^0 x M_N}\Biggl[\Biggl\{\sum_{\substack{m,\mathrm{occ}\\ j,\mathrm{all}}} e^{-iz^0E_m} - \sum_{\substack{m,\mathrm{all}\\ j,\mathrm{occ}}} e^{-iz^0E_j}\Biggr\}\frac{1}{E_m-E_j} \\
\times \langle m|\tau^b|j\rangle\,\langle j|\,(1+\gamma^0\gamma^3)\,\exp(-iz^0\hat{p}^3/2)\,\frac{\epsilon^{3ab}\Delta^a}{\boldsymbol{\Delta}_\perp^2}\,\exp(i\boldsymbol{\Delta}\hat{\mathbf{X}})\,\exp(-iz^0\hat{p}^3/2)\,|m\rangle \\
+iz^0\sum_{m,\mathrm{occ}} e^{-iz^0E_m}\langle m|\tau^b(1+\gamma^0\gamma^3)\,\exp(-iz^0\hat{p}^3/2)\,\frac{\epsilon^{3ab}\Delta^a}{\boldsymbol{\Delta}_\perp^2}\,\exp(i\boldsymbol{\Delta}\hat{\mathbf{X}})\,\exp(-iz^0\hat{p}^3/2)\,|m\rangle\Biggr]\,. \qquad \text{(B2)}
\end{aligned}$$

If we take out from the double sums the limiting case $E_m \to E_j$ and combine it with the respective single sums in (B1, B2) then we arrive at the expressions in Eqs. (28, 29).

1. $H_E(x,\xi,t)$

In order to demonstrate that at $t=0$ the moments of $H_E(x,\xi,t)$ are in fact functions of ξ only, we have to continue analytically the expression in Eq. (B1) to the unphysical point $t=0$. For that note that

$$\exp(i\boldsymbol{\Delta}\hat{\mathbf{X}}) = \sum_{l_e=0}^{\infty}\frac{(-i2\xi M_N)^{l_e}}{l_e!}|\hat{\mathbf{X}}|^{l_e}P_{l_e}(\cos\hat{\theta}) \qquad \text{(B3)}$$

where $\cos\hat{\theta} = \hat{X}^3/|\hat{\mathbf{X}}|$ and P_{l_e} are Legendre polynomials, *cf.* Ref. [17]. Taking moments of $H_E(x,\xi,t)$ in Eq. (B1) and using (B3) we obtain

$$\begin{aligned}
M_E^{(L)}(\xi,0) \equiv \int\limits_{-1}^{1}\mathrm{d}x\;x^{L-1}H_E(x,\xi,t) = -\frac{M_N N_c}{12IM_N^L}\sum_{l_e=0}^{\infty}\frac{(-i2\xi M_N)^{l_e}}{l_e!} \\
\times\Biggl[\sum_{L_i=0}^{L-1}\binom{L-1}{L_i}\sum_{J=0}^{L_i}\binom{L_i}{J}\frac{1}{2^{L_i}}\Biggl\{\sum_{\substack{m,\mathrm{occ}\\ j,\mathrm{all}}}E_m^{L-L_i-1} - \sum_{\substack{m,\mathrm{all}\\ j,\mathrm{occ}}}E_j^{L-L_i-1}\Biggr\}\frac{A^E_{mj}}{E_m-E_j} \\
-(L-1)\sum_{L_i=0}^{L-2}\binom{L-2}{L_i}\sum_{J=0}^{L_i}\binom{L_i}{J}\frac{1}{2^{L_i}}\sum_{m,\mathrm{occ}}E_m^{L-L_i-2}B^E_m\Biggr]\,, \qquad \text{(B4)}
\end{aligned}$$

with

$$A^E_{mj} \equiv \langle m|\tau^b|j\rangle\, \langle j|\, \tau^b(1+\gamma^0\gamma^3)\,(\hat{p}^3)^J\,|\hat{\mathbf{X}}|^{l_e}P_{l_e}(\cos\hat{\theta})\,(\hat{p}^3)^{L_i-J}\,|m\rangle\;,$$
$$B^E_m \equiv \langle m|3(1+\gamma^0\gamma^3)\,(\hat{p}^3)^J\,|\hat{\mathbf{X}}|^{l_e}P_{l_e}(\cos\hat{\theta})\,(\hat{p}^3)^{L_i-J}\,|m\rangle\;. \tag{B5}$$

Using the G_5-symmetry, cf. Eq. (A2), we obtain

$$A^E_{mj} \equiv (-1)^{L_i}\langle j|\tau^b|m\rangle\,\langle m|\,\tau^b(1-\gamma^0\gamma^3)\,(\hat{p}^3)^J\,|\hat{\mathbf{X}}|^{l_e}P_{l_e}(\cos\hat{\theta})\,(\hat{p}^3)^{L_i-J}\,|j\rangle\;,$$
$$B^E_m \equiv (-1)^{L_i}\langle m|3(1-\gamma^0\gamma^3)\,(\hat{p}^3)^J\,|\hat{\mathbf{X}}|^{l_e}P_{l_e}(\cos\hat{\theta})\,(\hat{p}^3)^{L_i-J}\,|m\rangle\;. \tag{B6}$$

Exploring these identities (for the first it is necessary to rename under the sum in (B4) $m \leftrightarrow j$) we see that A^E_{mj} and B^E_m in Eq. (B4) are effectively given by (note that $(\gamma^0\gamma^3)^N = 1$ for even N and $\gamma^0\gamma^3$ for odd N)

$$A^E_{mj} = \langle m|\tau^b|j\rangle\,\langle j|\,\tau^b(\gamma^0\gamma^3)^{L_i}\,(\hat{p}^3)^J\,|\hat{\mathbf{X}}|^{l_e}P_{l_e}(\cos\hat{\theta})\,(\hat{p}^3)^{L_i-J}\,|m\rangle\;,$$
$$B^E_m = \langle m|3(\gamma^0\gamma^3)^{L_i}\,(\hat{p}^3)^J\,|\hat{\mathbf{X}}|^{l_e}P_{l_e}(\cos\hat{\theta})\,(\hat{p}^3)^{L_i-J}\,|m\rangle\;. \tag{B7}$$

From parity transformations, cf. Eq. (A3), we conclude that $A^E_{mj} = B^E_m = 0$ if l_e is odd. Thus we observe that only even powers in ξ contribute to the moments. In the next step we demonstrate that the infinite series in ξ^2 is actually a polynomial.

For that let us first observe that the object $\tau^b|j\rangle\langle j|\tau^b$ (where summation over b is implied) is invariant under hedgehog rotations. Thus it is practically an irreducible spherical tensor operator of rank zero with respect to simultaneous isospin- and space-rotations [17]. So in both cases, A^E_{mj} and B^E_m, we deal with matrix elements of the type $\langle m|\hat{O}|m\rangle$, the only difference being the "replacement" $\tau^b|j\rangle\langle j|\tau^b \to 3$ which is irrelevant for our arguments. The matrix elements $\langle m|\hat{O}|m\rangle$ are non-zero only if the operator $\hat{O}$ is rank zero, cf. [17] for details. $\hat{O}$ is a product of $\hat{p}^a$, $\gamma^0\gamma^3$ which have rank 1, and P_{l_e} which is rank l_e, and rank zero operators. $\hat{O}$ is in general a reducible operator which, however, can be decomposed into a sum of irreducible tensor operators. For our purposes it is important to find the highest value for l_e in the Legendre polynomial which yields a non-vanishing result for $\langle m|\hat{O}|m\rangle$. The operators $\hat{p}^a$, which appear L_i-times in whatever ordering, and operator $\gamma^0\gamma^3$, for odd L_i, can combine to an operator with maximally rank L_i+1 for odd L_i (L_i for even L_i). Thus l_e can have at most rank L_i+1 for odd L_i (L_i for even L_i), otherwise the total operator $\hat{O}$ cannot reach the needed rank zero. Considering that $L_i \le (L-1)$ we see that the L^{th} moment of $M^{(L)}_E$ is a polynomial with the highest power ξ^L for even L (ξ^{L-1} for odd L). Thus we obtain

$$\begin{aligned}
&M^{(L)}_E(\xi,0) = \\
&-\frac{M_N N_c}{12 I M_N^L}\Bigg[\sum_{L_i=0}^{L-1}\binom{L-1}{L_i}\sum_{J=0}^{L_i}\binom{L_i}{J}\frac{1}{2^{L_i}}\sum_{\substack{l_e=0\\ l_e\ \text{even}}}^{L_i+1}\frac{(-i2\xi M_N)^{l_e}}{l_e!}\Bigg\{\sum_{\substack{m,\text{occ}\\ j,\text{all}}}E_m^{L-L_i-1}-\sum_{\substack{m,\text{all}\\ j,\text{occ}}}E_j^{L-L_i-1}\Bigg\}\frac{A^E_{mj}}{E_m-E_j} \\
&\quad -(L-1)\sum_{L_i=0}^{L-2}\binom{L-2}{L_i}\sum_{J=0}^{L_i}\binom{L_i}{J}\frac{1}{2^{L_i}}\sum_{\substack{l_e=2\\ l_e\ \text{even}}}^{L_i+2}\frac{(-i2\xi M_N)^{l_e-2}}{l_e!}\sum_{m,\text{occ}}E_m^{L-L_i-2}B^E_m\Bigg]\;.
\end{aligned} \tag{B8}$$

2. $E_M(x,\xi,t)$

In this case the relevant structure to be continued analytically to $t=0$ is, *cf.* Ref. [17],

$$\frac{\Delta^a_\perp}{\mathbf{\Delta}^2_\perp}\;\exp(i\mathbf{\Delta}\hat{\mathbf{X}}) = \sum_{l_e=2}^{\infty}\frac{(-i2\xi M_N)^{l_e-2}}{l_e!}[\hat{p}^a_\perp, |\hat{\mathbf{X}}|^{l_e}P_{l_e}(\cos\hat{\theta})]\;. \tag{B9}$$

With this result we obtain for the moments of $E_M(x,\xi,t)$ at zero t the result

$$\begin{aligned}
M^{(L)}_M(\xi,0) &\equiv \int_{-1}^{1}\mathrm{d}x\;x^{L-1}E_M(x,\xi,t) = \frac{iM_N^2N_c}{2IM_N^L}\sum_{l_e=2}^{\infty}\frac{(-i2\xi M_N)^{l_e-2}}{l_e!} \\
&\times\Bigg[\sum_{L_i=0}^{L-1}\binom{L-1}{L_i}\sum_{J=0}^{L_i}\binom{L_i}{J}\frac{1}{2^{L_i}}\Bigg\{\sum_{\substack{m,\text{occ}\\ j,\text{all}}}E_m^{L-L_i-1}-\sum_{\substack{m,\text{all}\\ j,\text{occ}}}E_j^{L-L_i-1}\Bigg\}\frac{A^M_{mj}}{E_m-E_j} \\
&-(L-1)\sum_{L_i=0}^{L-2}\binom{L-2}{L_i}\sum_{J=0}^{L_i}\binom{L_i}{J}\frac{1}{2^{L_i}}\sum_{m,\text{occ}}E_m^{L-L_i-2}B_m\Bigg]\;,
\end{aligned} \tag{B10}$$

with

$$\begin{aligned} A^M_{mj} &\equiv \langle m|\tau^b|j\rangle \, \langle j| \, (1+\gamma^0\gamma^3) \, (\hat{p}^3)^J \, \epsilon^{3ab}[\hat{p}^a_\perp, |\hat{\mathbf{X}}|^{l_e} P_{l_e}(\cos\hat{\theta})] \, (\hat{p}^3)^{L_i-J} \, |m\rangle \ , \\ B^M_m &\equiv \langle m|\tau^b \, (1+\gamma^0\gamma^3) \, (\hat{p}^3)^J \, \epsilon^{3ab}[\hat{p}^a_\perp, |\hat{\mathbf{X}}|^{l_e} P_{l_e}(\cos\hat{\theta})] \, (\hat{p}^3)^{L_i-J} \, |m\rangle \ . \end{aligned} \tag{B11}$$

From the G_5-symmetry, cf. Eq. (A2), we obtain

$$\begin{aligned} A^M_{mj} &= \langle m|\tau^b|j\rangle \, \langle j| \, (\gamma^0\gamma^3)^{L_i+1} \, (\hat{p}^3)^J \, \epsilon^{3ab}[\hat{p}^a_\perp, |\hat{\mathbf{X}}|^{l_e} P_{l_e}(\cos\hat{\theta})] \, (\hat{p}^3)^{L_i-J} \, |m\rangle \ , \\ B^M_m &= \langle m|\tau^b \, (\gamma^0\gamma^3)^{L_i+1} \, (\hat{p}^3)^J \, \epsilon^{3ab}[\hat{p}^a_\perp, |\hat{\mathbf{X}}|^{l_e} P_{l_e}(\cos\hat{\theta})] \, (\hat{p}^3)^{L_i-J} \, |m\rangle \ . \end{aligned} \tag{B12}$$

From parity transformations, cf. Eq. (A3), it follows that A^M_{mj} and B^M_m are zero if l_e is odd. Thus we observe again that only even powers in ξ contribute to the moments.

In order to demonstrate that the infinite series in even powers of ξ is actually a polynomial, let us consider first the double sum contribution in Eq. (B10). We deal with the matrix elements A^M_{mj} which are of the type $\langle m|\tau^a|j\rangle\langle j|\hat{O}^a|m\rangle$. The operator τ^a is an irreducible spherical tensor operator of rank 1 with respect to simultaneous isospin- and space- (hedgehog-) rotations [17]. Thus only certain transitions $\langle m|\tau^a|j\rangle$ between the states $|m\rangle$ and $|j\rangle$ are non-zero. In order for the entire expression for A^M_{mj} to be non-zero the same transitions must appear also in the piece $\langle j|\hat{O}^a|m\rangle$, thus the operator $\hat{O}^a$ must be rank 1, too.

The operators τ^a, $\hat{p}^a$, $\gamma^0\gamma^3$ and P_{l_e}, which in our context are relevant for the rank counting, can combine to an operator with maximally rank L_i+2 for even L_i (L_i+1 for odd L_i). Thus l_e can be at most L_i+3 for even L_i (L_i+2 for odd L_i), otherwise the total operator $\hat{O}^a$ cannot reach the needed rank 1. However, l_e must be even, thus $l_e \leq (L_i+2)$ for even L_i (L_i+1 for odd L_i). Finally $L_i \leq (L-1)$. Therefore the double sum contribution to the L^{th} moment of $M^{(L)}_M$ is a polynomial with the highest power ξ^{L-2} for even L (ξ^{L-1} for odd L).

B^M_m in Eq. (B12) is zero unless the operators ($|\hat{\mathbf{X}}|$, τ^a, the L_i+1 operators $\hat{p}^a$, P_{l_e}, and $\gamma^0\gamma^3$ if L_i is odd) combine to a rank 0 operator. One obtains the same restriction for the maximal value of l_e in term of L_i as above, however, in this case $L_i \leq (L-2)$. Thus, we finally obtain (with A^M_{mj}, B^M_m given in Eq. (B12))

$$\begin{aligned} & M^{(L)}_M(\xi,0) = \\ & \frac{iM_N^2 N_c}{2IM_N^L}\Bigg[\sum_{L_i=0}^{L-1}\binom{L-1}{L_i}\sum_{J=0}^{L_i}\binom{L_i}{J}\frac{1}{2^{L_i}}\sum_{\substack{l_e=2\\ l_e\ \mathrm{even}}}^{L_i+2}\frac{(-i2\xi M_N)^{l_e-2}}{l_e!}\Bigg\{\sum_{\substack{m,\mathrm{occ}\\ j,\mathrm{all}}} E_m^{L-L_i-1}-\sum_{\substack{m,\mathrm{all}\\ j,\mathrm{occ}}} E_j^{L-L_i-1}\Bigg\}\frac{A^M_{mj}}{E_m-E_j} \\ & \quad -(L-1)\sum_{L_i=0}^{L-2}\binom{L-2}{L_i}\sum_{J=0}^{L_i}\binom{L_i}{J}\frac{1}{2^{L_i}}\sum_{\substack{l_e=2\\ l_e\ \mathrm{even}}}^{L_i+2}\frac{(-i2\xi M_N)^{l_e-2}}{l_e!}\sum_{m,\mathrm{occ}} E_m^{L-L_i-2}B^M_m\Bigg] \ . \end{aligned} \tag{B13}$$

We know that $(H^u+H^d)(x,\xi,t)$ satisfies polynomiality and that its even moments L are polynomials of degree L [17]. Here we observe that even moments L of $E_M(x.\xi,t)$ are polynomials of degree $(L-2)$. Since $E_M(x,\xi,t)$ is the sum of $(E^u+E^d)(x,\xi,t)$ and $(H^u+H^d)(x,\xi,t)$ this means that the moments of $(E^u+E^d)(x,\xi,t)$ also satisfy polynomiality and that the coefficients of the highest power ξ^L of even moments satisfy the relation (5).

APPENDIX C: PROOF OF THE SPIN SUM RULE

The model expression for the second moment of $E_M(x,\xi,t)$ is given by (B13) for $L=2$. By observing that $[\hat{p}^a_\perp, \hat{\mathbf{X}}^2 P_2(\cos\hat{\theta})] = i\hat{X}^a_\perp$ we obtain

$$M^{(2)}_M(\xi,0) = -\frac{N_c}{4I}\Bigg[\sum_{\substack{m,\mathrm{occ}\\ j,\mathrm{all}}}\frac{(E_m+E_j)\langle m|\tau^b|j\rangle \, \langle j| \, (\gamma^0\gamma^3)\epsilon^{3ab}\hat{X}^a_\perp|m\rangle}{E_m-E_j}+\sum_{\substack{m,\mathrm{occ}\\ j,\mathrm{non}}}\frac{2\langle m|\tau^b|j\rangle \, \langle j| \, \hat{p}^3\epsilon^{3ab}\hat{X}^a_\perp \, |m\rangle}{E_m-E_j}\Bigg] \ . \tag{C1}$$

Using the following identity, where we explore the equations of motion in the model,

$$\langle j| \, (E_m+E_j)\gamma^0\gamma^3 \, \hat{X}^j_\perp|m\rangle = \langle j| \, \Big\{H \, , \, \gamma^0\gamma^3 \, \hat{X}^j_\perp\Big\} \, |m\rangle = \langle j| \, \Big(2\hat{p}^3\hat{X}^j_\perp + i\gamma^j\gamma^3\Big) \, |m\rangle \tag{C2}$$

we obtain

$$M^{(2)}_M(\xi,0) = \frac{N_c}{2I}\sum_{\substack{m,\mathrm{occ}\\ j,\mathrm{non}}}\frac{1}{E_m-E_j}\Big[\langle m|\tau^3|j\rangle \, \langle j| \, \gamma^0\gamma^3\gamma_5|m\rangle + 2\langle m|\tau^3|j\rangle \, \langle j|\epsilon^{3ab}\hat{X}^a\hat{p}^b|m\rangle\Big] \ . \tag{C3}$$

In Eq. (C3) we identify the model expressions for the spin S^Q and angular momentum L^Q contribution of quarks and antiquarks to the spin of the nucleon S^N

$$
\begin{aligned}
S^Q &\equiv \frac{N_c}{2I}\sum_{\substack{m,\text{occ}\\ j,\text{non}}}\frac{1}{E_m-E_j}\langle m|\tau^3|j\rangle\,\langle j|\gamma^0\gamma^3\gamma_5|m\rangle = \frac{1}{2}\,g_A^{(0)}\;,\\
L^Q &\equiv \frac{N_c}{I}\sum_{\substack{m,\text{occ}\\ j,\text{non}}}\frac{1}{E_m-E_j}\langle m|\tau^3|j\rangle\,\langle j|\epsilon^{3jk}\hat{X}^j\hat{p}^k|m\rangle\;,
\end{aligned}
\tag{C4}
$$

where $g_A^{(0)}$ denotes the isosinglet axial coupling constant. The operators in (C3) can be added according to Eq. (A1)

$$
\frac{1}{2}\gamma^0\gamma^3\gamma_5+\epsilon^{3jk}\hat{X}^j\hat{p}^3=\hat{S}^3+\hat{L}^3=\hat{K}^3-\hat{T}^3\;. \tag{C5}
$$

Noting that in Eq. (C3) the matrix elements $\langle j|\hat{K}^3|m\rangle = K^3_j\delta_{jm}$ vanish we obtain

$$
M_M^{(2)}(\xi,0)\equiv 2S^Q+2L^Q=\frac{N_c}{4I}\sum_{\substack{m,\text{occ}\\ j,\text{non}}}\frac{1}{E_j-E_m}\langle m|\tau^3|j\rangle\,\langle j|\tau^3|m\rangle = 1\;. \tag{C6}
